The writer has not examined the results obtained by the proposed formula sufficiently to express an opinion on its reliability under different conditions. It is admittedly somewhat awkward of direct application, but this practical difficulty is overcome by the use of diagrams, which is a sensible procedure in almost any case. Referring to Plate XIII, giving the frequency of 1-hour rainfalls of different intensities, it may be well to mention that the New York curve is based on records of the greatest single intensity for each month of observation, and that other high intensities were not recorded. For this reason, it is probable that the frequencies shown by this curve are slightly below the actual.

The author is to be congratulated on having produced, after so careful a study, a formula free from some of the objections found in those proposed heretofore.

MEMOIRS OF DECEASED MEMBERS.

NOTE.—Memoirs will be reproduced in the volumes of *Transactions*. Any information which will amplify the records as here printed, or correct any errors, should be forwarded to the Secretary prior to the final publication.

JAMES LEWIS FRAZIER, M. Am. Soc. C. E.*

DIED FEBRUARY 28TH, 1914.

James Lewis Frazier was born at Oakenwold, the fine estate of his father, at Staunton, Va., on June 17th, 1849. He was descended from the Scotch-Irish of the Shenandoah Valley, of Virginia, on both sides of the house. His father was William Frazier, of Staunton, an alumnus of Yale College and the University of Virginia, whose forbears came to Virginia from Ulster, Ireland. His mother was Sue Massie Lewis, of the sixth line of descendants from John Lewis, founder of Augusta County and Staunton, and his wife, Margaret Lynn Lewis, the daughter of the Laird of Loch Lynn in Scotland. John Lewis also came to Virginia from Ulster, Ireland; his sons, Gen. Andrew Lewis, Col. Charles Lewis, and Col. William Lewis, were conspicuous in Colonial and Revolutionary wars. Mr. Frazier was descended from Col. William Lewis (who was called the "Civilizer of the Border" during Colonial times), and his beautiful wife, Anne Montgomery.

His early education was under the direction of Dr. Junius, a French tutor at Oakenwold. Later, he went to Washington College, at Lexington, Va., and was there prepared for the University of Virginia under Gen. Robert E. Lee, then in charge of the college; he was a classmate there of Mr. Julius Kruttschnitt. He received his engineering education at the University of Virginia, and was a classmate of the late Samuel Spencer, M. Am. Soc. C. E.

Mr. Frazier was engaged on the location and construction of the Alabama Great Southern Railway, and the Chesapeake and Ohio Railway in the early Seventies, and was later associated with the late L. G. F. Bouscaren, M. Am. Soc. C. E., in the construction of the Cincinnati Southern Railway. He was also connected with the location and construction of many other lines of railroad.

In 1882, he was made General Superintendent of the Chesapeake and Ohio Southwestern Railway, with headquarters at Louisville, Ky. It was there that he married Miss Caroline Robinson, in 1887. In 1889, he was sent by the late Collis P. Huntington, F. Am. Soc. C. E., to the Southern Pacific Railway, and, under Vice-President Towne, was Superintendent, at various times, of most of the important divisions. At the request of one of the Directors of the Southern Pacific Railway, who was also interested in the Toledo, St. Louis and

*Memoir prepared by R. Montfort, M. Am. Soc. C. E.

Western Railway, he became General Manager of that road for two years. He was then made General Manager of the California Northern, and returned to San Francisco.

As the result of an attack of pleurisy while in San Francisco, Mr. Frazier was left with serious heart trouble and retired from active work. He spent the last nine years of his life traveling with his wife, mainly in Europe. He died in Rome, Italy, on February 28th, 1914, after a short illness. His remains were interred at Louisville, Ky., the former home of his wife.

He had no children, but, being of a sunny disposition, was especially fond of them.

Mr. Frazier was an accomplished engineer and a born leader, endowed with all the energy, honesty, and courage of his long line of Virginia ancestors. His modest, lovable disposition endeared him to his many friends and associates who will ever remember him with affection.

Mr. Frazier was elected a Member of the American Society of Civil Engineers, on September 1st, 1880, and served as a Director from the Pacific Coast District from 1902 to 1904.

JUSTUS HERBERT GRANT, M. Am. Soc. C. E.*

DIED AUGUST 1ST, 1914.

Justus Herbert Grant was born in Auburn, N. Y., on June 19th, 1849. His first engineering experience was obtained in 1866 and 1867, as Rodman on the preliminary and location surveys for the Southern Central Railroad.

In 1867, he entered the Sheffield Scientific School of Yale University, from which he was graduated in the class of 1870 with the degree of Ph. B.

In 1871, he served as Levelman and Topographer on the surveys for the Utica, Chenango and Cortland Railroad, from Cortland to Otselic, N. Y., and during a part of 1872, as Levelman and Assistant Engineer in charge of the construction of a short, narrow-gauge line, in Chenango County, N. Y., known as the Central Valley Railroad.

In 1872 and 1873, Mr. Grant was employed as Levelman on the preliminary surveys for the Auburn and Homer Midland, and Canandaigua, Palmyra and Ontario Railroads.

From 1874 to 1876, he was a member of the Engineer Corps of the New York Central and Hudson River Railroad, serving as Assistant Engineer in charge of earthwork and masonry construction

* Memoir prepared by Charles H. Grant, Esq., supplemented by information on file at the Society House.

of 16 miles and of the track-laying and ballasting of 32 miles of the line between Syracuse and Rochester, N. Y.

In the Fall of 1876, he resigned to accept a position as Engineer with the firm of George H. Thompson and Company, Contractors, of Rochester, N. Y., and as such was in charge of laying out and superintending the construction of all the work of that firm. In 1885, on the death of Mr. G. H. Thompson, the firm was dissolved, and Mr. Grant associated himself with the late H. M. Ellsworth, as the firm of Ellsworth and Grant, Contractors. This firm built many of the largest buildings in the city, including the Chamber of Commerce, the new Central Church, the Andrew Street Bridge, and the West High School.

In 1900 and 1901, Mr. Grant served as Commissioner of Public Works of Rochester, and in 1904 he was appointed Assistant City Engineer, in which capacity he served the city until his death on August 1st, 1914.

Mr. Grant was one of the most solid and influential business men of Rochester, of which city he had been a resident since 1874. His record and reputation in his profession were of the highest order, and he was regarded by his associates as one of the distinguished engineers of the United States.

He was a Trustee of the Mechanics Institute, and one of the founders of the Rochester Builders' Exchange, having served as its Secretary for many years. He was also a Director of the National Association of Builders; a member of the Permanent Arbitration Board of the Builders' Exchange; a member of the Brick Layers', Plasterers', and Stone Masons' Union; a Trustee of the Rochester Home for the Friendless; a Trustee of the Unitarian Church; and a member of the University Club of Rochester.

Although the community apparently has lost a devoted servant, a citizen of public spirit and of pride in its progress and advancement, his presence will be always felt, his exemplary life will be always an inspiration to those who knew him and loved him, and his work will go on.

Mr. Grant was elected a Member of the American Society of Civil Engineers, on March 2d, 1892.

DAVID ERNEST MELLISS, M. Am. Soc. C. E.*

DIED MARCH 24TH, 1913.

David Ernest Melliss was born in New York City, on March 11th, 1848. His professional education was received at the School of Mines of Columbia College, in that city, where he pursued the regular course

* Memoir prepared by Bolton B. Melliss, Esq.

in Mining Engineering for three years. Early in 1867, he matriculated at the University of Goettingen, in Hanover, Germany, and, after two years, which were chiefly devoted to chemistry, physics, geology, and mineralogy, he was graduated with the degree of Doctor of Philosophy in 1869. The following year, he attended lectures in the Natural Science Course at the University of Vienna. He was afterward constantly engaged in professional work, chiefly as a Consulting Civil and Mining Engineer, in the course of which he examined professionally and reported on mineral lands in the United States, Europe, Mexico, and Central America.

In 1873, Mr. Melliss was in charge of a topographical and geological survey of the Provinces of Guanacasta and Nicoya, for the Costa Rica Government. In 1881, he was appointed Consulting Engineer to the Pacific Gas and Electric Company, of San Francisco, Cal., and in its interest visited the principal gas-works of the United States, England, France, and Belgium, for the purpose of studying and reporting on the different processes.

The plans for the buildings and wharves of the Union Iron Works of San Francisco were designed by him and carried out under his supervision, as were also those for the Arctic Oil Works, which were built of concrete masonry throughout and completed in 1884.

The water-works of Mazatlan, Mexico, with its pumping plant, two double reservoirs, 22 miles of steel mains, and the entire city distributing system, were designed by Mr. Melliss, and constructed under his supervision from the inception of the enterprise to its completion in 1890. For several years he acted as Consulting Engineer to the Guadelupe de los Reyes Mining Company, the most important mining concern in Sinaloa, and he was also the Administrator of the San José de las Bocas Mines.

He was also engaged in considerable work in Venezuela, and, in recognition of certain professional services rendered that Government, was decorated with the Order of the Bust of Bolivar.

While in Mazatlan, in 1899, he complied with the request of the United States Minister to Guatemala, Mr. Mizner, to accompany him and act as Secretary of Legation during his visit to Nicaragua and Costa Rica.

Mr. Melliss' next important engineering work was the plant of the Olympic Salt Water Company, of San Francisco, representing an investment of about $500 000, every detail of which was designed and erected under his supervision.

In 1895, he acted as Superintendent of Works of the New City Hall Commissioners of the City of San Francisco, and at the same time followed his profession as Consulting Engineer. In this capacity (as Engineer), he remained until about 1904, when the pressing need of greater attention to his own affairs induced him to withdraw from

active life at a comparatively early age. In this manner, he spent the remaining years of his life.

In the middle of March, 1913, he was stricken with pneumonia, from which he never recovered, his death occurring at Mill Valley, Cal., on March 24th.

Mr. Melliss was elected a Member of the American Society of Civil Engineers on October 2d, 1895.

ARTHUR LOUIS PHILLIPS, M. Am. Soc. C. E.*

DIED JULY 13TH, 1914.

Arthur Louis Phillips was born in DuPage County, Illinois, on April 8th, 1864. He was educated at St. Ignatius College, Chicago, from which he was graduated in 1884. He immediately entered the service of the Chicago, Burlington and Quincy Railway, as a Rodman on construction in Missouri and Minnesota, and remained with that Company for two years. From 1886 until 1889 he was employed by the Northern Pacific Railway as Leveler on surveys in Montana and Washington. He was then promoted to the position of Resident Engineer. In 1889, he was appointed an Assistant Engineer on maintenance of way on the Southern Pacific Railway, with headquarters at Houston, Tex. In 1890-91-92 he was in the employ of the Denver and Rio Grande Railway as Resident Engineer and Locating Engineer.

On the opening of the Cherokee Strip, in Oklahoma, in 1893, Mr. Phillips was one of the first engineers in the field, and located many miles of the railway now forming parts of the Frisco System, being engaged on this work until July, 1899, when he entered the service of the Mexican Central Railway as Locating Engineer. He remained in that position until November, 1902, when he returned to Oklahoma and until March, 1903, was engaged on the location and construction of the Fort Smith and Western Railway.

In 1903 Mr. Phillips returned to the employ of the St. Louis and San Francisco Railroad, remaining with that Company until 1908, during which time he made surveys for the proposed extensions from Memphis to New Orleans, and was in charge of construction of the Frisco terminals in the latter city. He attained the position of Assistant Chief Engineer of the Frisco Railroad during this time, and made two trips to Mexico for the purpose of reconnoitering a proposed extension of the St. Louis, Brownsville and Mexico line from Brownsville to Vera Cruz. He was also sent to South America by some New York interests to look over a proposed railway in Colombia, which, however, was not built.

* Memoir prepared by F. G. Jonah, M. Am. Soc. C. E., and Clinton H. Fisk, Assoc. M. Am. Soc. C. E.

From November, 1908, until March, 1912, Mr. Phillips was engaged in private practice as Consulting Engineer in New Orleans, La. He then accepted a position as Chief Engineer of The Cuba Railroad, with headquarters at Camaguay, Cuba. He remained with this Company until June, 1913, and then resigned to accept a position as Assistant Chief Engineer of the Tela Railroad Company, in Honduras. On the completion of the location surveys for that work, he returned to New Orleans, and in December, 1913, reopened an office as Consulting Engineer. Shortly thereafter his health began to fail, and the last few months of his life were spent at various health resorts, but he declined rapidly, his death occurring in Denver, Colo., on July 13th, 1914. The body was taken back to New Orleans for interment.

On September 30th, 1905, Mr. Phillips was married, in Chicago, Ill., to Miss Jessie Fleming, who survives him.

He was a most courteous and affable gentleman, very considerate to, and greatly beloved by, his subordinates. He was a splendid Spanish scholar, and his experience in Latin-American countries had enabled him to speak the language fluently.

Mr. Phillips was elected a Member of the American Society of Civil Engineers on November 4th, 1903. He was a Thirty-second degree Mason and a Shriner, and was also a Member of the American Railway Engineering Association.

HORACE ARTHUR COOK, Assoc. M. Am. Soc. C. E.*

DIED MAY 17TH, 1914.

Horace Arthur Cook was born in Miller, Ind., on April 4th, 1877. He was graduated from Valparaiso University, in 1896, with the degree of B. S., and in the Fall of that year began work as Rodman on road construction in Lake County, Indiana. From September, 1897, to September, 1901, he was employed as telegraph operator, cashier, and agent for the Baltimore and Ohio Railroad, in Ohio and Indiana, and for the Northern Pacific Railway, in Washington.

In September, 1901, he entered Purdue University, from which he was graduated with the degree of Bachelor of Science in Civil Engineering in 1904. In June, 1909, he received the degree of Civil Engineer from the same University.

From August, 1904, to July, 1905, he was employed as Rodman, Field Draftsman, and Transitman, respectively, on the Galena and Wisconsin Divisions of the Chicago and Northwestern Railway, and from July to November, 1905, he served as Transitman, and Assistant Engineer in charge of 18 miles of construction, on the Wyoming and

* Memoir prepared by O. P. M. Goss, Assoc. Am. Soc. C. E.

Northwestern Railway. In December, 1905, he resigned his position with the Wyoming and Northwestern Railway Company to go to Seattle, Wash., where he was engaged, as Field Engineer for the Seattle Engineering Company, on various projects and surveys for hydro-electric developments, and in February, 1907, he was made a member of the firm and Vice-President of the Company.

In October, 1908, Mr. Cook's health failed, and he was forced to abandon his Seattle practice and move to Phœnix, Ariz., where he again engaged in general engineering work. He organized the Phœnix Engineering Company, of which he was President, and built a number of structures. Later, he made a specialty of road construction, in which branch of the profession he attained marked success and worked up quite an extensive consulting practice.

In 1906, he was married to Cora May Caulkins, of Lafayette, Ind., who, with one daughter, survives him.

Mr. Cook was a man of fine character, and his opinions and conclusions were highly respected by other members of the Profession. He had an exceptionally pleasing personality and was loved by all who knew him.

While at college, he took an active part in athletics, making a good record in the pole vault. He belonged to the Tau Beta Pi Fraternity and to the Order of Masons, and was also a member of the Pacific Northwest Society of Engineers.

Mr. Cook was elected an Associate Member of the American Society of Civil Engineers, on May 3d, 1910.

WILLIAM DE HERTBURNE WASHINGTON, Assoc. M. Am. Soc. C. E.*

DIED AUGUST 30TH, 1914.

William de Hertburne Washington was born at Clover Sea, Hanover County, Virginia, on June 29th, 1863. He was the son of Lewis W. and Ella Basset Washington, and was a descendant of Charles, a brother of George Washington.

Mr. Washington was educated at Mary Schools and spent a term at college in special technical and mathematical study. He was to have entered the United States Navy, but no vacancy occurring at the time, he secured employment, on March 1st, 1880, on a preliminary survey for The Coal and Iron Railroad, in West Virginia, attaining the position of Instrumentman. The following year he was engaged as Assistant Engineer on the West Virginia Central and Pittsburgh Railway, and spent another year or more getting out timber and prospecting for ores and minerals on the lines of the Norfolk and Western and Chesapeake and Ohio Railways.

* Memoir prepared by Ernest Abs-Hagen, Esq., supplemented by information on file at the Society House.

Mr. Washington then came to New York City and was employed for some time in the office of the Chief Engineer of the American Atlantic and Pacific Ship Canal Company (the original Nicaragua Canal Company), and in other mechanical engineering work. In October, 1885, he was appointed United States Consul at London, Ont., Canada, and, in addition to his official duties, was allowed to act as representative of the firms of Messrs. Andrew Brothers, and Ferris and Walladay, Water-works Engineers and Contractors, reporting on and negotiating for the construction of water-works or hydraulic plants at Toronto, St. Thomas, Chatham, etc.

On his return to New York City, Mr. Washington organized the Hydraulic Contracting Company which built the water-works at Conneaut, Ohio, and hydraulic plants at many other places. When the firm was dissolved, he organized and became President and General Manager of the Hydraulic Construction Company which designed and constructed forty very important industrial plants in the United States.

After remaining in the construction business for about ten years, Mr. Washington went into the development of real estate, and at the time of his death, was President of the New Center Company, the Eastern Warehouse and Realty Company, etc.

In 1913, he was appointed Consulting Engineer to the Highway Commission of the State of New York, by Governor Sulzer, and was a Delegate to the Third International Road Congress, held that year in London, England. After the adjournment of the Congress, he visited various European countries for the purpose of inspecting roads and pavements, and on his return to the United States, made an elaborate report on his observations to the State Highway Commission.

Mr. Washington had recently published a book entitled "Progress and Prosperity," which embodied a comprehensive study of the mediums of development by the influence of railroad and highway transportation. He was also a contributor to the discussion on "Road Construction and Maintenance" before this Society in January, 1914.

He was the organizer and President of the West Virginia State Society, a member of the Sons of the Revolution, the Southern Society, the Virginia Historical Society, the American Society of Mechanical Engineers, the American Institute of Mining Engineers, and a Fellow of the National Geographical Society. He was also a member of, and until a short time before his death made his home at, the Calumet Club, in New York City.

Mr. Washington had just returned to New York City after a trip to Canada when he was stricken with cerebro-spinal meningitis, and died August 30th, 1914, after a short illness. His body was taken to Charlestown, W. Va., and interred in the family cemetery there.

He was unmarried, and is survived by a nephew and two sisters.

Mr. Washington was elected an Associate Member of the American Society of Civil Engineers on October 5th, 1892.

SUBMERGED PIPE WORK AT PORTLAND, OREGON.

By D. D. Clarke, M. Am. Soc. C. E.

To be Presented December 16th, 1914.

Synopsis.

In the following pages reference is made to the experience of the Water Department of the City of Portland, Ore., in supplying a portion of the city by means of several flexible-joint pipes laid under the bed of the Willamette River, a navigable stream passing through the central portion of the city.

The present gravity supply for the city is taken from the Bull Run River, a mountain stream within the limits of the Bull Run Reserve, which adjoins the Oregon National Forest, in the Cascade Mountains, and is brought thence to the eastern border of the city through two steel conduits 24 miles in length, one 33 to 42 in. in diameter, built in 1893 and 1894, and one 44 to 52 in. in diameter, completed in 1911.

The supply for the West Side or main business district is brought across the city through a 32-in. cast-iron main, the river being crossed by one 24-in. and one 30-in. flexible-joint steel main.

The object of this paper is to describe the pipes laid for the river section of this West Side conduit, the method of construction, and the cost, as well as the steps taken subsequently for the repair and reconstruction of the submerged pipes, as originally laid.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

The work described covers:

(1) The laying of a 28-in. cast-iron, flexible-joint pipe in 1894.
(2) The laying of a 24-in. steel, flexible-joint pipe in 1898.
(3) The repair of the 28-in. cast-iron, flexible-joint pipe in 1909.
(4) The laying of a 30-in. steel, flexible-joint pipe in 1911.
(5) The work undertaken during 1913 and now just completed, consisting in taking up and relaying at greater depth the 24-in. line originally laid in 1898, and taking up and storing for future use at another point the 28-in. cast-iron pipe laid in 1894.

In further explanation of the paper, the writer desires to say that in making a search of engineering literature a few years ago he was able to find comparatively few references to flexible-joint pipes of the larger sizes, and therefore he has felt under obligation to place his experience within reach of engineers interested in this subject. For these reasons the following notes have been prepared and submitted.

28-Inch Line.—The pipe laid in 1894 (Plate XXX) consisted of 2 006 ft. of 28-in., cast-iron, flexible-joint pipe, 1½ in. thickness of shell, in net laying lengths of 15 ft. 8 in.

The contract price for furnishing this pipe was a lump sum for a certain specified length, which equalled	$31.4275	per lin. ft.
The contract for laying	2.50	" " "
Dredging, 18 746 cu. yd. at 40 cents	3.738	" " "
Total	$37.6655	per lin. ft.

or for 2 006 lin. ft. of 28-in., flexible-joint pipe, in place, a total of $75 556.

During 1894 the Water Department labor wage in Portland was $1.75 per day.

For details regarding this work reference is made to the paper* by Franklin Riffle and the late Albert S. Riffle, Members, Am. Soc. C. E., entitled "A Line of 28-In. Cast-Iron Submerged Pipes Across the Willamette River, at Portland, Ore." This paper and the discussions thereon are exceedingly interesting and instructive.

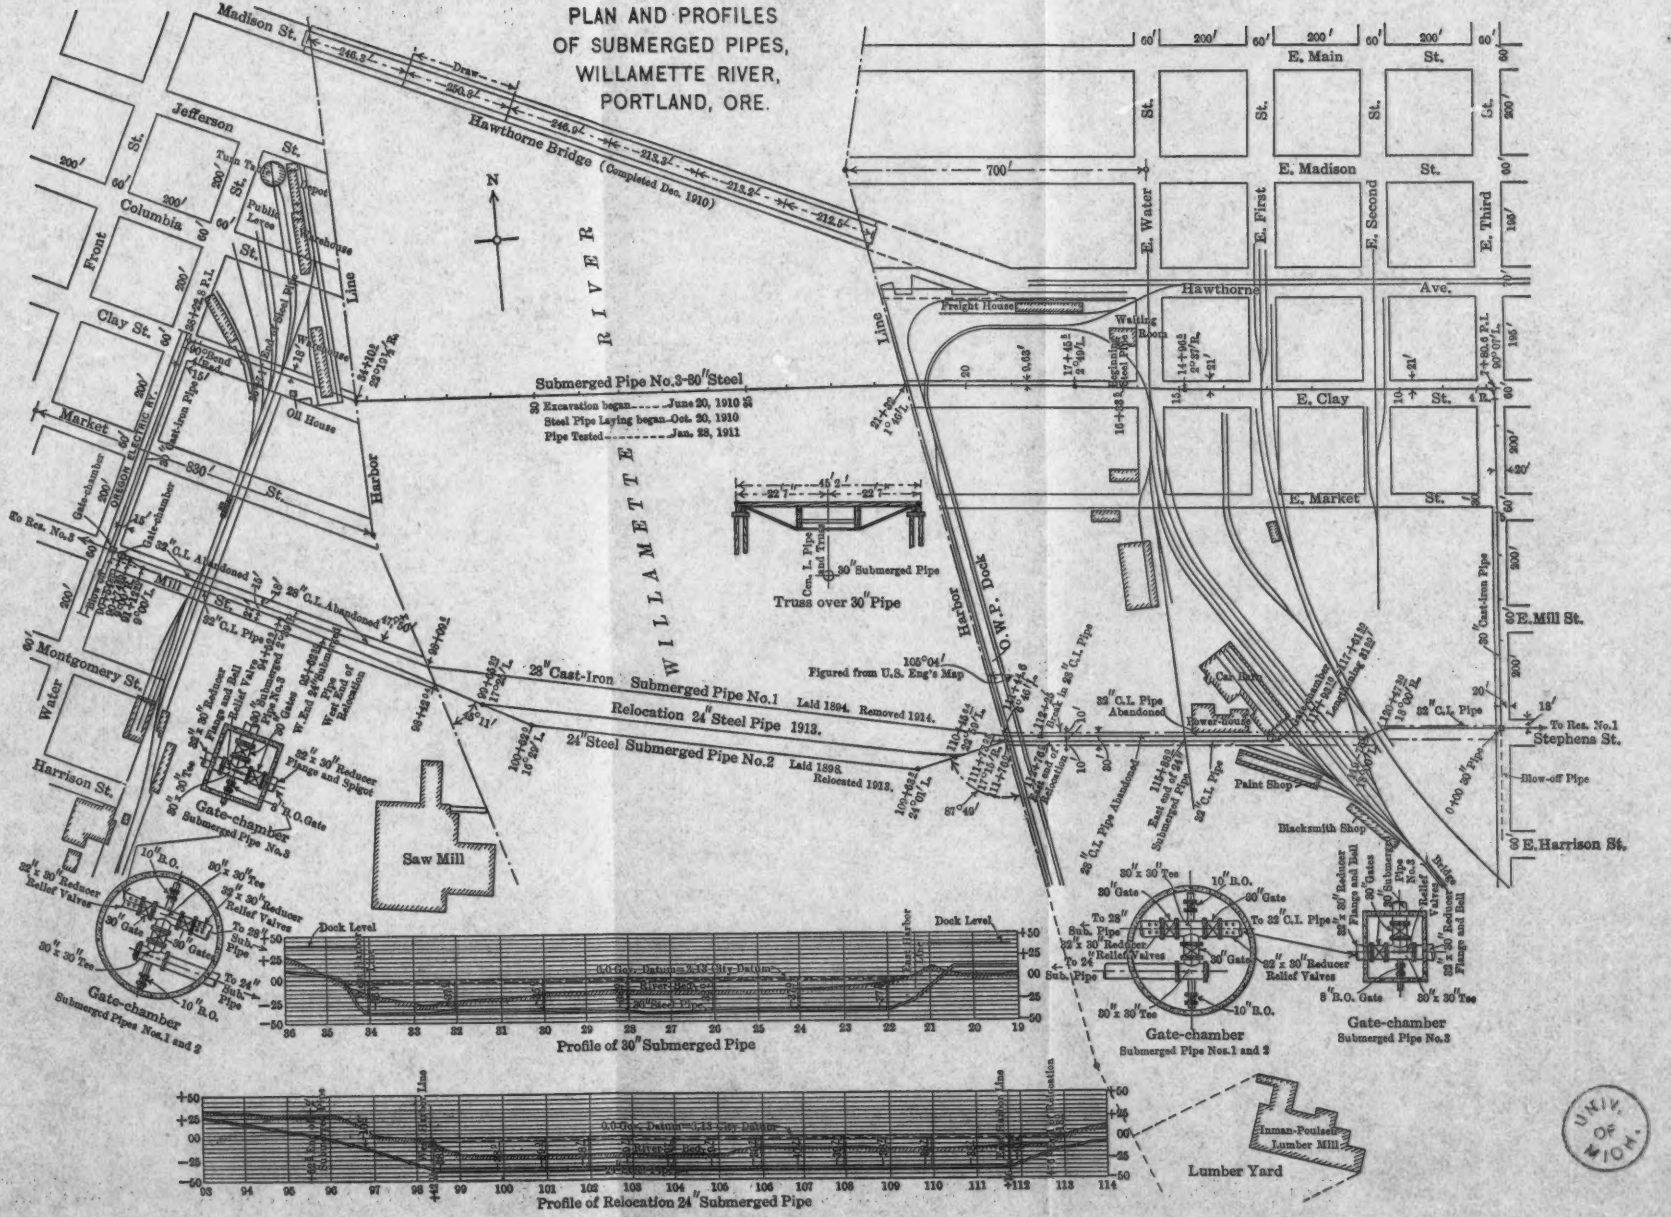
SUBMERGED PIPE WORK.

PLAN AND PROFILES OF SUBMERGED PIPES, WILLAMETTE RIVER, PORTLAND, ORE.



UNIV. OF MICH.

24-Inch Line.—The second pipe, the 24-in. submerged line laid in 1898, consisted of 2 041.6 lin. ft. of lap-welded steel pipe, ⅜-in. plate, including fifty-eight flexible joints, of special design, placed at intervals varying from 20 to 40 ft., depending on the alignment and grade of the pipe trench.

Messrs. Smyth and Howard, of Portland, Ore., were the general contractors for this work, the contract prices being as follows (including two joints and 72 lin. ft. of pipe not used):

60 flexible joints, $260.00 each	$15 600.00
1 938 lin. ft. of 24-in. pipe, $8.50 per lin. ft.	16 472.32
15 332 cu. yd. dredging, $0.40 per cu. yd.	6 132.80
2 041.6 lin. ft. pipe-laying, including joints, $1.77 per lin. ft.	3 613.63
Total	$41 818.75

During 1898 the Water Department labor wage in Portland was $1.75 to $2.00 per day.

This work was undertaken in the late summer, after the subsidence of the June freshet in the Columbia (which sometimes causes a rise of 20 ft. or higher at Portland), and was completed the same season.

The methods and appliances adopted for this work were similar to those adopted in laying the 28-in. line, 4 years before. A ladder-dredge was used in excavating the pipe trench, and the excavated material was taken away on barges to be utilized in filling low ground adjacent to the harbor line in another portion of the city. A cradle was also used in laying the pipe in the excavated trench, as described in the paper by Messrs. Franklin and Albert S. Riffle.

The flexible joint used (Fig. 1) was made in Portland, from designs prepared by the Water Department. Plate XXXI shows the cradle with which the pipe was laid.

The pipe, after it was laid, was tested in a manner similar to that adopted for the 28-in. line in 1894. The results secured did not indicate that the pipe was absolutely tight, but they were accepted at the time as being the best that could be obtained. The final test, under a pressure of from 170 to 180 lb., showed a leakage of approximately 7 gal. per min., or 10 080 gal. per day, or about 8 gal. per lin. ft. of joint, per day, under the pressures noted, which are approximately 50% in excess of the normal working pressure.

The location selected for this pipe (Fig. 2) was parallel to and approximately 10 ft. from the 28-in. line, until the harbor line was reached on each side of the river. The line was then deflected southward, or up stream, until a point was reached 100 ft. from the 28-in. line, which it paralleled for the remaining distance.

The profile of the original line shows a 22 to 24-ft. channel, 100 ft. or more in width, near the west shore, and, for the larger part of the distance thence to the east harbor line, the low-water depth did not exceed 12 to 16 ft. In establishing the grade for the original line, it was decided first to place the pipe in an open trench dredged to a depth of 8 ft. below the bed of the stream, a cover of 4 ft. being thus provided which was deemed ample to protect the pipe from injury by the passing or anchoring of vessels. In view of the existence of at least a 23 to 24-ft. channel adjacent to the west harbor line, which it was thought would provide for all shipping interests in that portion of the harbor (being at the head of deep-water navigation), it was not thought necessary to incur the extra expense required to dredge a trench to the depth of 30 ft. or more below low water for the entire distance between harbor lines. The matter was compromised, therefore, by placing the pipe grade so as to permit of dredging a channel at least 16 ft. in depth at all points within the harbor limits. This required dredging in places to a depth of from 12 to 14 ft. with at least an 8-ft. trench at all points. The original pipe line (the 28-in.) was laid on a grade established as just described, and the second pipe (the 24-in.) also conformed to the same grade, as nearly as practicable.

For each of the pipe lines heretofore mentioned the flexible-joint portion was a little more than 2 000 ft. in length (2 006 ft. for the 28-in. and 2 041.6 ft. for the 24-in. line). This length covered the distance from river bank to river bank and reaching a point where the grade of the pipe trench was above low-water level in the river. For several hundred feet additional on each side of the river, standard cast-iron pipe was laid to a connection with a concrete gate-chamber, where the two pipes were united with one 32-in. line forming a section of the main Bull Run Conduit for the supply of the West Portland District, the total distance between the east and west gate-chambers being 2 706 ft., and the approximate distance between harbor lines being 1 335 ft.

Repair of 28-Inch Line.—As has been stated, the 28-in. line was completed in 1894 and the 24-in. line in 1898. It was then thought

that the double line would provide amply for all the needs of the West Side District for a long term of years, and that, by means of the two lines, the possibility of any interruption to the supply was practically eliminated. In fact, such a feeling of security existed for more than 9 years, or until a sudden break in the 28-in. line caused all dreams of security to vanish.

The break in this main was discovered early on the morning of April 10th, 1909, when it was found that the water had been falling in the City Park Reservoir, No. 3, which was then being supplied through the broken main. Not being able to find any trace of a leak along the street mains leading to the river, the attention of the inspectors was turned to the submerged pipe crossing. Signs were then discovered of an under-water break at a point near the east shore and about 100 ft. back from the established harbor line, then built up with a dock owned and operated as a part of the terminal system of the Oregon Water Power and Railway Company, then operating a short line of railway leading from Portland to the valley of the Clackamas, a distance of about 40 miles.

It was impossible at first to tell in which line the break had occurred, as both the 28-in. and the 24-in. lines were in service at the time. Therefore it became necessary to shut the gates at each end of first one and then the other of the two submerged pipes, in order to see if the pressure on the main would come up again and the flow become re-established.

The first trial not proving successful, the foreman in charge, in opening the gate that had just been closed and in closing those on the other line, became confused, in the haste and excitement of the moment, with the result that one of the gates shutting off the broken section was not fully closed, the effect being still to allow so much water to escape as to hold down the pressure far below normal. The conclusion immediately reached was that both pipes were broken.

No sooner was this condition reported to the Superintendent than he at once made arrangements for starting the pumps at the Palatine Hill Pumping Station, in order to supply the West Side District, the entire west side storage at that time being only about 35 000 000 gal., or approximately 2 days' supply available for all points. The Palatine pumps were started at about 10.00 A. M. on April 11th, for the first time since they were shut down on January 2d, 1895.

FIG. 2.

The pumping of Willamette River water into the city mains in the West Side District, as was done during 3 days (April 11th to 13th, inclusive), was unfortunate and, as it proved, entirely unnecessary, for, when the broken pipe was so nearly uncovered that one pipe could be distinguished from the other, the true condition of affairs was discovered, namely, that the 28-in. pipe was the only line broken.

Fortunately, no harm came from the infusion of Willamette River water into the city mains, although at one time it was feared that a typhoid epidemic might result. On the renewal of the Bull Run gravity supply, the pumps were shut down, the reservoirs and distribution mains were promptly flushed, and no unusual sickness was reported.

The cause of the break, so far as conditions have been diagnosed, was no doubt due to the strain caused by an unequal settlement of the pipe brought about by a gravel fill, 16 ft. or more in depth, which had been deposited over the pipe by the owners of the adjoining property. The pipe line right of way at this point was only 30 ft. in width. The railway company owning the property on each side used a suction dredge to fill in its property between the shore and the harbor line. This was done at the time of the June high water, when the entire tract was submerged. The dredged material was deposited at some little distance from the city property, but when the freshet had subsided it was found that the filled material had taken a very flat slope under water, and had actually buried the submerged pipes to a considerable depth. In the paper by Messrs. Franklin and Albert S. Riffle is noted the fact that "On the east side the bed of the river consisted of boulders and hard pan firmly cemented together," and it was at the point where this material was encountered in the pipe trench that the break occurred, presumably caused, as has been suggested, by the pipe not having a uniform bearing on the trench bottom, and hence being unequally loaded by the weight of the increased depth of fill.

It was the removal of the overlying deposit of sand and gravel which was largely responsible for the delay in uncovering and repairing the broken pipe, which was not completed until October 11th.

At first a clam-shell dredge was used in the removal of this material, but, later, a suction dredge produced more satisfactory results, the flat slope taken by this material under water greatly increasing the volume of the excavation required. When the pipe was uncovered sufficiently to admit of examination by a diver, it was found that one of the 15 ft. 8-in. lengths of the 28-in. cast-iron pipe had been frac-

tured diagonally, the break being about 12 ft. in length and extending from a point within a few inches of one bell joint for about three-fourths of the full length of the pipe section, and crossing the pipe from one side to the other, leaving a point about 1 ft. in width at the end of each fragment. These two pieces were separated about 3 ft. by the force of the jet at the time the break occurred, the pressure at this point being about 150 lb. per sq. in.

In no case were the balls injured, but the fracture came so near to them that it was not possible to use a band or sleeve that did not cover the entire length of the fractured pipe, together with a ball at each end.

When the condition of the pipe was ascertained, the engineer reported the facts to the Water Board and suggested a possible method of repair. In view of the proximity of the 28-in. to the 24-in. pipe at the point where the break occurred, and the necessity for securing a continuous supply for the West Side without danger of interruption through the failure of the 24-in. line, the engineer decided that the safest plan would be to uncover the 28-in. line in the river at a point about 100 ft. from the east harbor line (the distance between the two pipes being approximately 75 ft.), and there, by means of the diver, make an under-water connection with the main and lay a new main thence to the east shore of the river, where a junction could be made with the old line above water level.

This would have required about 400 ft. of new pipe, which could have been quickly made of steel plates in local shops, and could have been laid from a platform along the north line of the pipe line tract. The only work in connection therewith requiring the services of a diver would have been the making of the joint with the old main in front of the harbor line. It was planned so that the use of three or four joints would have been sufficient for laying that portion of the pipe which would have been below water level. The estimated cost of this work was approximately $9 500.

The foregoing did not meet with the approval of the Water Board, owing largely to the cost, and it was therefore abandoned for the plan of constructing a split sleeve and encasing a full length of the broken pipe in its original bed, including a flexible joint at each end, the divers giving assurances that they could make the necessary joints under water.

Owing to the fact that at the point where the break occurred the

two pipes were near to one another (approximately only 2 ft. between them for a short distance) and that the broken pipe was also about 2 ft. lower than the 24-in. steel pipe which must be kept in service, it was determined that, prior to undertaking the repair work, and in order to protect the 24-in. main thoroughly, a row of timber sheet-piling should be driven between the two pipes, so as to avoid any danger of undermining the steel main by the excavation for the broken pipe. The pressure on this main being approximately 150 lb. at the bed of the river, it was decided to reduce this considerably before the piles were driven. This was done by shutting down the flow during the day, when the work of pile-driving was in progress, and turning it on again at night in order to maintain the supply in the City Park Reservoirs. One hundred and ten 9 by 12-in. "Wakefield" piles were driven, which occupied 5 days, and on the completion of this work, the additional dredging required to expose the 28-in. line fully was undertaken.

Preparatory to placing the split sleeve designed for this purpose (Fig. 3), the ends of the broken pipe were lifted partly from the position in which they were found, and also moved horizontally a short distance from the sheet-piling in order to give room for the sleeve. The fractured ends of the pipe were drawn together as closely as possible and then wired in place and afterward wrapped in heavy tarred canvas, securely fastened, the object of the latter being to prevent the cement grouting placed inside the sleeve from gaining admission to the interior of the pipe.

The sleeve was designed to be built of riveted steel plates, of sufficient diameter and length to take in an entire length of the pipe, with a flexible joint at each end. This meant that the main barrel of the sleeve must be about 4 ft. in diameter and 16 ft. long, with a reducer at each end, diminishing from 4 ft. to a diameter of about 32 in. at each end in a distance of about 3 ft., thus fitting the outside of the 28-in. pipe, making the extreme length over all 22 ft.

A contract for the construction of this sleeve was awarded to the Moran Company for $1 026.50, and it was placed by Department forces. The weight of the sleeve was 14 100 lb.

The progress of the work was delayed by the high stage of water due to the June flood in the Columbia River, and time was also required to secure the necessary materials and manufacture the sleeve. The sleeve was not received until September 8th, but the placing of it

was commenced immediately thereafter. The work of placing the sleeve, caulking the joints, testing the pipe, and grouting the space between the sleeve and the pipe occupied the time from September 8th to October 11th, and on October 12th the main was reported as being again ready for service.

For the longitudinal seams rubber packing was used, but the end joints were caulked with lead wool, or shredded lead, which was held in place by a steel ring fitting closely around the pipe and bolted to the sleeve.

In making the test for leakage, the small force pump used in testing the pipe could not raise the pressure to more than 40 lb. per sq. in. and maintain it in the full length of the river crossing, the estimated leakage being at the rate of 119 500 gal. per day on the entire line between the gates—a distance of 2 706 ft. In February, 1910, it was again tested, and the leakage was noted as 38 000 gal. in 24 hours; a third test, in December, 1911, showed a decrease to 25 000 gal. per day under normal working pressure. When first tested, no leakage could be observed through the joints of the sleeve, and the matter was allowed to rest, as it was not considered of sufficient importance to warrant further investigation and expense.

It cannot be claimed that this work was done at small expense, or in an especially economical manner, the exigencies of the case demanding all possible speed without undue regard to cost.

The work of uncovering the pipe was delayed on account of its proximity to the railway dock, a section of which had to be taken out in order to admit the dredges; and, besides, it was necessary to exercise care not to injure the pipe during the dredging operations.

The dredges were engaged by the day, and the total cost for them, including towage and removal of docks, etc., amounted to	$2 850.00
The split sleeve cost, f. o. b., Portland	1 026.50
Placing and grouting the sleeve, including the sheet-piling and timber platform, cost	3 138.00
For the services of divers, who were in constant attendance while the pipe was being uncovered and the sleeve was being put in place, the allowance was	2 250.00
The total cost of the repairs, including the items just mentioned and incidental expenses, was	$10 750.00

Lowering the Pipes.—As already stated, the grade for the first pipes laid was established so as to provide for an available channel depth of only 16 ft. over the central portion of the upper harbor. It was not then anticipated that the development of the manufacturing and shipping interests in the southern part of the city would demand increased facilities so quickly.

As early as 1902, a demand was made on the Water Committee for the lowering of the central portion of the two pipes, in order to admit of a channel being dredged on a direct line from the draw-span of the Hawthorne Avenue Bridge to the Inman-Poulsen Company mill—a large lumber manufacturing plant on the east side. Complaints and demands of a similar character were made nearly every season thereafter, but no action was taken thereon, except to call on the engineer for reports and estimates of cost.

In 1911 it finally became manifest that the shipping interests in the upper harbor would soon require improved facilities, and it was also learned that the plans of the Port of Portland and the United States Government engineers called for a 30-ft. channel in the upper harbor above the Hawthorne Bridge, it being claimed that this would suffice for the future needs of the Port in that direction, regardless of the depths that will ultimately be required in the lower Willamette and Columbia Rivers, where even now a 40-ft. channel is dreamed of and talked about by the commercial bodies of the city and State as among the possibilities of the next few years.

Investigations and studies undertaken in connection with this work developed the fact that to lower the two submerged pipes so as to give a 30-ft. depth at low-water stage would practically necessitate the lowering of the pipes for the entire distance between harbor lines, approximately 1 335 ft., together with an additional distance at each end to provide for the approaches to the lower level, or a total of at least 1 500 ft. This would involve a large quantity of dredging, in addition to the adjustment of the pipes in the new trench.

The first plan prepared called for the construction of a series of pile bents of two piles each, with timber caps and ties, placed at intervals equal to one pipe length, from which the pipe could be suspended by slings, and rods with threads of sufficient length to permit the pipe to be lowered into the new position after the supporting earth had been removed and the new trench excavated. It was thought that the

necessary excavation could be made from the side of the pipe with a suction dredge which could be manipulated so as to undermine the pipe gradually and admit of lowering it.

This plan was abandoned later, owing, in part, to the difficulty in handling the dredged material which had to be barged away and disposed of outside of the river channel.

The method finally adopted called for taking up the two pipes and, after making necessary repairs, relaying them in the trench excavated to the required level, as described later.

30-Inch Line.—After considering the difficulties attending the lowering of the two pipes and the danger of breaking one or both of them, and the consequent interruption of the supply for the entire West Side, or main business district of the city, the Water Board decided that, in the interests of safety, a new and entirely separate submerged pipe line should be laid in advance of any work which might in any manner disturb the two pipes then in use. Plans and specifications were therefore prepared by the office staff calling for a 30-in. line crossing the river at the foot of Clay Street, or approximately 600 ft. distant from the two pipes already in use.

The new line was planned to leave the 32-in. supply main at a point about 400 ft. east of the original East Side gate-chamber at 3d and Stephens Streets, and to connect again with the 32-in. main at the West Side gate-chamber at Water and Mill Streets.

This plan called for 4 312.6 ft. of entirely new pipe. Of this, 2 265.6 ft. on the east and west sides were to be standard, 30-in., cast-iron pipe, Class "F", New England Water Works Association specifications, and the remaining 2 047 ft. were to be 30-in., lap-welded, galvanized and asphalted steel pipe, of $\frac{7}{16}$-in. plate with flange joints. Inserted in the steel main, at intervals of about 40 ft., were placed twenty-seven flexible joints of cast iron.

The grade established for the pipe trench between the harbor lines was 38 ft. below low-water level, which provided for a 3 to 4-ft. cover over the top of the pipe, with a 30-ft. depth of channel, as called for by the plans of the Port of Portland and the U. S. Engineers.

This work was commenced in August, 1910, and completed in March, 1911.

The dredging of the trench for this main was commenced by one of the suction dredges operated by the Port of Portland Commission,

at a rental of $250 per day. The work with this dredge was soon discontinued, however, as it was needed for channel work at another point, and the dredging was completed with the dipper-dredge owned by the Pacific Bridge Company, this Company being in a position to utilize the dredged material for filling purposes in a near-by district.

The 30-in., standard, cast-iron pipe used for the shore connections was manufactured by the Oregon Iron and Steel Company, at its foundry near Portland, the price, in place, being $11.10 per ft.

The flexible joints were made by the John Wood Iron Works, of Portland, from plans furnished by the Water Department, for $345 each.

The 30-in., lap-welded steel, galvanized and asphalted pipe was purchased from the National Tube Company (2 200 ft.) at $14 per ft.

The contract for laying the pipe and making the joints was awarded to Robert Wakefield and Company, of Portland, for the prices given in Table 1.

TABLE 1.—Cost of Pipe Laying.

Summary of Total Costs:

Steel pipe	$29 135
Dredging	20 318
Cast-iron pipe and pipe laying	65 747
Labor and engineering	4 868
Total	$120 008
Original estimate	125 000

On the completion of the work, the pipes, including the standard cast-iron and flexible-joint steel pipe, were tested to 175 lb. per sq. in., and the leakage under the normal pressure of 150 lb. was found to be approximately 30 000 gal. per day.

Having become satisfied that this loss was from no one leak of special size, but rather from a number of small leaks, no attempt was made to check them. It may be stated that the last test was made on September 28th, 1912, when the seepage loss was at the rate of 5 000 gal. per day—a decrease of 25 000 gal. per day from that which occurred shortly after the main was laid.

Lowering of 24-Inch Line.—Soon after the completion of the new line, in 1911, a renewed application was made by the milling interests and the Port of Portland Commission, for the removal of the original submerged pipe lines, which were claimed to be a serious obstruction to navigation in the upper harbor.

An attempt was made to induce the Port of Portland Commission to share in the expense of this work, at least to the extent of contributing the use of its dredges for the removal of the material which it would be necessary to excavate to uncover the pipe and prepare the new trench at a lower level, but the inability of the Water Department to secure a satisfactory dumping ground prevented the consummation of the arrangement finally agreed upon, namely, that the Port of Portland would deduct from the sum due for the use of its dredges (at $350 per day) a sum sufficient to cover the cost of dredging a channel 300 ft. wide at the submerged pipe crossing a distance of 100 to 200 ft. on the line which had been planned, extending from the draw-span toward the upper river channel. This comprised a very small part of the total work required for this channel, which had been laid out in such a position as to oblige the city to lower its pipes for the entire distance between harbor lines, the natural deep-water channel near the west harbor line having been entirely ignored.

The conclusion of the whole matter was a decision of the Water Board to advertise for bids for the entire work, independent of any promise or expectation of aid from any source. It was furthermore decided to ask for proposals, on a unit basis, for the necessary dredging and the disposal of the dredged material; for uncovering and taking up both the 28- and 24-in. pipes; and for relaying the 24-in. pipe only—the 28-in. pipe to be stored for future use at some other crossing.

It was deemed that the two steel pipes, 30 and 24 in. in diameter, respectively, would provide an ample supply for the West Side District, the estimated capacity of the two pipes being nearly 40% in excess of that of the 32-in. line forming the shore ends of the submerged

PORTLAND, ORE.

pipes and connected with the city reservoirs, and therefore the relaying of the 28-in. cast-iron main would not be necessary or advisable under the circumstances.

Proposals were invited for doing the work on a unit basis, but a contract was finally awarded to Mr. A. C. U. Berry, of Portland, for the lump sum of $69 400, this being a considerable reduction from the unit prices bid, and to include the necessary dredging and the disposal of the material; the taking up and relaying of the 24-in. line; and the taking up of the 28-in. line. All necessary repairs to the 24-in. line before relaying were to be done by force account (actual cost plus 10 per cent.).

The actual cost of this work to the Department, as shown by the final estimate, equals $80 785, divided as follows:

85 000 cu. yd. sand and gravel dredging. 6 060 cu. yd. shore excavation..... 1 725 ft. 24-in. steel pipe removed..... 1 630 ft. 28-in. cast-iron pipe, removed. 1 714 ft. 24-in. steel pipe, relaid.....	Agreed price:	$69 400
Extras, at cost plus 10% profit. Repairs to forty-nine ball and socket joints for 24-in. pipe, including cleaning, machining, testing, painting, etc.....		3 438
Repairs to 1 714 ft. of 24-in. pipe, including cleaning, painting, repair of flanges, testing, etc., together with 808 lin. ft. of new riveted steel pipe, 24-in., at $5.15 per ft.....		8 458
Miscellaneous extras.....		478
		$81 774
Deduct for breakage of pipe by contractor, and for minor supplies furnished by city.....		989
Net amount of contract.....		$80 785

The test of the 24-in. line, since relaying in new position, compares favorably with the original tests when the pipe was first laid, in 1898, the maximum leakage being 2 100 gal. per day.

The 28-in. pipe, completed in 1894, was built under the direction of the late Col. Isaac W. Smith, M. Am. Soc. C. E., Chief Engineer of the Water Committee, Emery Oliver, M. Am. Soc. C. E., being the Assistant Engineer in immediate charge of the work for the city. The flexible joints used for the 24-in. line, completed in 1898, were

designed by the late J. A. Lesourd, mechanical engineer, of Portland, W. W. Amburn, M. Am. Soc. C. E., was the Assistant in charge of the dredging and pipe laying. The joints used for the 30-in. line, built in 1911, were made from plans prepared by W. R. Phillips, M. Am. Soc. C. E., also of Portland. The laying of the 30-in. line was under the direction of F. M. Randlett, Assoc. M. Am. Soc. C. E., Assistant Engineer, Water Department; and the taking up of the two pipes in 1913, and the relaying of one of them, was also under the direction of Mr. Randlett with B. S. Morrow, Assoc. M. Am. Soc. C. E., Assistant in immediate charge of the work.

The writer was also connected with the work described, first as Principal Assistant Engineer in charge of pipe lines for the Bull Run gravity supply, completed in 1894, and since 1897 as Engineer in charge of all construction operations for the Portland Water Department, now organized as the Bureau of Water, Department of Public Utilities, Will H. Daly, Commissioner in Charge.

Since the foregoing was prepared the writer has read the able and instructive article on Flexible Joints for Submerged Pipe Lines,* by Emil Kuichling, M. Am. Soc. C. E., who has made an exhaustive study of the subject, and by his presentation of the matter has placed the Profession under obligations therefor. The data he has gathered regarding the several types of flexible joints heretofore in use, and his conclusions drawn therefrom, form a valuable reference for all who may hereafter have occasion for investigation along similar lines.

HISTORY OF LITTLE ROCK JUNCTION RAILWAY BRIDGE, OF THE ST. LOUIS, IRON MOUNTAIN AND SOUTHERN RAILWAY COMPANY, OVER THE ARKANSAS RIVER AT LITTLE ROCK, ARKANSAS, 1883-1914.

By C. E. Smith, M. Am. Soc. C. E.

To be Presented December 16th, 1914.

Synopsis.

Object.—This paper was written for the purpose of informing the Engineering Profession of the troubles encountered at the Little Rock Junction Railway Bridge, due to the defective construction of the piers, in order that such defective construction may be avoided in the future; its purpose is also to point out the methods suggested and used to accomplish the correction of the defects, in order to guide the Profession in the correction of similar defects which may cause trouble in future in similar piers.

Digest.—The bridge consists of three 253 ft. 4-in., through truss spans, one 127 ft. 11-in., through truss span, and one 352 ft. 10-in., through truss swing draw-span, all single-track, resting on masonry piers and one abutment. Four of the piers are supported on pneu-

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

matic caissons and timber cribs. The pneumatic caissons are of ordinary timber construction, and rest on bed-rock, approximately 45 ft. below low-water line.

The timber cribs over the pneumatic caissons, extending up to low water, consist of 12 by 12-in. timbers, 3 ft. from center to center, sheeted outside with 3-in. planks. The spaces between the timbers were supposed to have been filled with rip-rap, but only a small quantity was placed, the greater number of the cavities having been filled with sand discharged from the caissons.

The caissons were poorly located, and when the working chambers were finally sealed, the tops of the timber cribs were considerably out of place. As the steel superstructure was on the ground at the time of the commencement of the masonry work, the masonry piers were located on top of the cribs in such a way that the coping courses were the proper distances apart to receive the steelwork, which made it necessary to place the piers at one side or the other of the timber cribs and use different batters.

The bed of the Arkansas River is composed of fine sand and silt, which is scoured to great depths during floods, especially around obstructions such as piers. The scouring of the river around these piers caused the sand to run out of the cribs through the spaces between the sheeting planks, and the timbers, being deprived of the support of the filling material, settled under the weight of the bridge and traffic.

As the masonry piers were not located concentrically with the cribs, the timbers compressed unequally and caused the piers to lean, their tops moving in various directions. The piers were a constant source of trouble and expense from the date of construction in 1883 until recently when they were reconstructed.

The reconstruction consisted in placing annular pneumatic caissons around the old piers, filling the spaces in the old cribs with concrete, enlarging the footing by filling in with concrete over the new annular caissons, and encasing the old piers in reinforced concrete following symmetrical lines, and enlarged for a double-track superstructure in the future.

The excessive scour of the Arkansas River renders practically impossible the maintenance of falsework for long periods, and swift run-outs have been experienced in all months. As the hazard attending

the maintenance is very great, the work was carried out without falsework.

The paper also describes in detail the various investigations to which this bridge was subjected by engineers, and the various unsuccessful attempts, made at great expense, to correct the trouble in advance of the final reconstruction.

Conclusions.—Timber cribs extending from pneumatic caissons to low-water level are entirely unsuitable for bridge pier foundations unless they are of solid timber construction, or, preferably, if the spaces between the timbers are carefully packed full of rock and thoroughly grouted, or, best of all, if the spaces are filled carefully with concrete and well rammed so as to fill all voids.

When defects are discovered in bridge piers, and trouble results, correction should be applied at the seat of the trouble; expenditures for temporary expedients are a waste of money. The continuation of the trouble without adequate correction involves constant hazard which can be avoided by efficient engineering talent.

Descriptive.

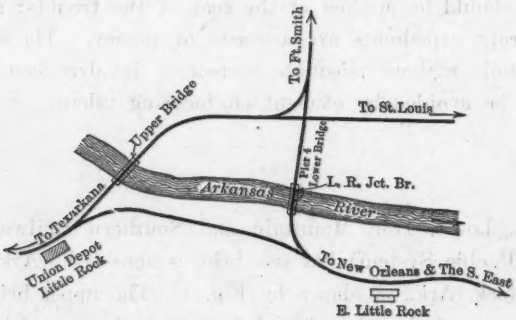
The St. Louis, Iron Mountain and Southern Railway Company (Missouri Pacific System) has two bridges across the Arkansas River at Little Rock, Ark., as shown by Fig. 1. The upper bridge, resting on pneumatic cylinder piers founded on rock, is crossed by main-line freight and passenger trains from points northeast of Little Rock to Texas and the Southwest. The lower bridge, founded on masonry piers, timber cribs, and pneumatic caissons on rock, is used by freight trains only from northeastern points to Louisiana and Southeastern Arkansas. Plate XXXII gives an elevation of this structure, commonly known as the Little Rock Junction Bridge. It consists of one 352 ft. 10-in. swing draw-span, three 253 ft. 4-in. simple truss spans, and one 127 ft. 11-in. simple truss span and trestle approach, all single-track, built in 1883. Fig. 2 is a view of the structure. The south abutment is of masonry built on the rock that outcrops on the south bank. The pivot pier, commonly known as Pier 2, and Piers 3, 4, and 5, are rock-faced, concrete-filled, masonry piers, about 45 ft. high, resting on filled timber cribs and pneumatic caissons about 40 ft. high, the masonry of the draw-pier being annular, with

a well down to the crib. Piers 6 and 7, are rock-faced, concrete-filled, masonry piers built on piles. The only specifications that can be found for the piers are as follows:

"The piers to rest on pneumatic caissons sunk to rock filled with concrete, timber cribbing to reach from roof of caissons to 4 ft. below low-water mark.

"This crib to be drift-bolted and planked on outside and filled with sand and stone; on this crib the masonry to be started and built up to grade line.

"Piers to be 6 ft. 6 in. wide under coping and 20 ft. long, with semicircular ends, with a batter of ½ in. per ft. on sides and up-stream ends, but no batter on down-stream ends; piers to consist of solid walls, averaging 2 ft. thick, built of dimension stone so as to make joints not exceeding ½ in.; inside space to be filled with concrete. This refers to three piers.



LOCATION OF LITTLE ROCK JUNCTION BRIDGE, LITTLE ROCK, ARK.

FIG. 1.

"Draw-pier to be 30 ft. in diameter under coping, with 8-ft. wall; center to be left open; pier to rest on caissons sunk to rock and filled with concrete with crib as before.

"Fifth pier on east bank to rest on piles sawed off and capped below low-water mark; to be 6 ft. 6 in. wide under coping and 20 ft. long, with semicircular ends, to have a batter of ½ in. per ft. on sides, but no batter on ends; in other respects to be the same as Piers 1, 2, and 3. All work to be done in a thorough workmanlike manner and to the satisfaction of the General Manager of the Little Rock Junction Railway.

"The draw protection and draw-pier to be completed by the first day of June, 1884, and all the work embraced in this contract to be completed by the first day of September, 1884, unless some disaster by flood or by other uncontrollable cause shall prevent.

FIG. 2.—LITTLE ROCK JUNCTION BRIDGE, LITTLE ROCK, ARK.

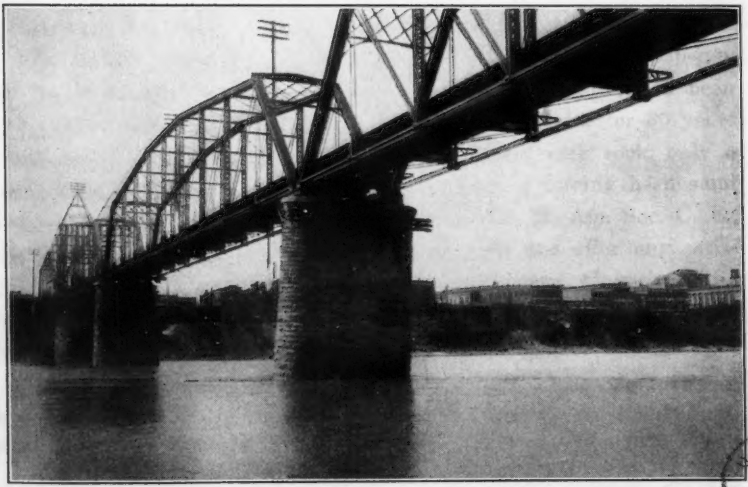

FIG. 3.—PIER 4 AFTER APPLICATION OF YOKES.

"Modifications may be made in these plans and specifications upon the request in writing by the General Manager of the Little Rock Junction Railway, and these modifications shall be complied with by the Contractors, but if the modifications increase the cost of the work, such increased cost shall be paid to the contractors."

The spans were so well designed and constructed that they are now safely carrying the present-day heavy engines and trains, and will continue to do so for many years. The design and construction of the south abutment and of Piers 6 and 7 were good and well executed. The design of the four pneumatic piers, although not in accordance with the best present-day practice, was adequate, but the construction was so faulty that trouble was experienced with them from the first, and the efforts that have been made during a period of 30 years to correct the defects resulted in a sequence of events that partook of the nature of a farce comedy in the face of impending disaster, which latter was narrowly averted.

There was nothing unusual or defective about the design or construction of the caissons, but they were very poorly located and carelessly controlled during sinking, resulting in their having been founded considerably out of place—from 2 to 3 ft. in one or two cases. The timber cribs, extending vertically upward from the caissons, reflected at their tops the improper location of the caissons.

The design evidently contemplated filling the cribs with rip-rap, and for 25 years it was not believed that any other filling had been used. After that time, however, it was suspected, and after 30 years it was learned, that, instead of having been filled with rock, only a small quantity had been used, most of the filling having been sand discharged from the caisson. C. de la C. Purdon, M. Am. Soc. C. E., who was inspector during the construction, does not offer any satisfactory explanation regarding the small percentage of rock filling and large percentage of sand filling, a letter from him in reference thereto reading as follows:

"The piers were built with ordinary caissons, and the caissons themselves filled with concrete. Above the caisson to about 4 ft. below the low-water mark, a crib was built. The timbers were either 3 ft. centers or 3 ft. clear—I don't remember exactly which—being all 12 by 12, and the spaces between these timbers, instead of being filled with concrete as is customary, were filled with rip-rap and then sand washed in. I objected to this strongly at the time, but as I

did not design the piers, this work being done by the late Mr. T. E. Sickels, I was not responsible for them. I told Mr. Wood at the time that I was satisfied the timbers would eventually crush and put the piers out of shape, which it seems occurred."

This does not entirely explain the trouble. Had the cribs been properly filled, the rip-rap filling every part, and then with sand washed into the interstices of the rip-rap, little, if any, settlement would have taken place. Very little rip-rap was placed, the greater part of the filling being sand, and, when this leaked out, the small quantity of rip-rap settled through the cribs, leaving the timbers to carry all the load. No satisfactory explanation has been found for filling the cribs with sand instead of stone.

The incorrect location of the caissons and cribs was discovered before starting the masonry, and as the spans were on the ground, the errors in location were corrected partly by placing the masonry piers to one side or the other of the cribs, partly in the batter of the piers, and partly in the placing of the bed-plates on the pier tops.

Pier 4 was built near the north edge of the crib and given equal batter on the two sides, and Pier 3, the north rest pier of the draw-span, was built near the center of the crib; but the north face was given a batter of 1½ in. per ft., and the south face was built plumb; the draw-span barely got a bearing on Pier 3, and the next fixed span reached well over on the pier.

Fig. 4 shows the location of the footing courses of Piers 3 and 4 with reference to the tops of the cribs, the cross-section of Pier 4, and the location of the intermediate span from Pier 3 to Pier 4.

Early Trouble.

The early record of the trouble is not clear, but it appears that, immediately after the completion of the bridge, the pivot pier under the draw-span (Pier 2) and Pier 4 began to settle and lean. As the bed of the Arkansas River is composed of fine sand which scours and shifts greatly during floods, it was thought that the settling was due to scour, the opinion immediately being formed that the cutting edges had not been founded on rock. Consequently, large quantities of rip-rap were unloaded around the piers, only to be washed down stream in following floods and requiring replacement. In addition, from time to time as necessity arose, the spans were

shifted back and forth, to keep their bearings on the piers, the tops of which had been made so small that very little variation could be permitted. The movement of the pivot pier was quite pronounced, and necessitated frequent leveling and adjustment of the draw-span, at great expense.

The matter was the subject of continual correspondence between the various officers, and, in reply to inquiry as to the best manner of strengthening the piers, Chief Engineer James W. Way, on December 6th, 1897, recommended as follows:

"Replying to your inquiry as to best method of proceeding with the work of strengthening the foundations of the pivot pier and pier 4 (numbering from the south) of the Little Rock Junction Bridge across the Arkansas River at Little Rock.

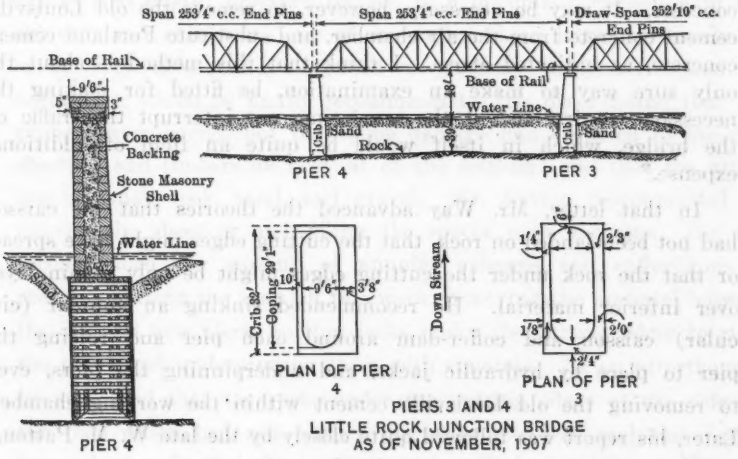

FIG. 4.

"One theory which may be presented for consideration is that the caissons are not properly landed on bed-rock, or possibly they may be faulty in construction and have spread at the cutting edges or on the corners. Again, it may be that what was termed bed-rock and believed to be such when the caissons were put in place, was but a thin stratum of shale overlying softer material; and that the respective weights of the piers, with their loads have caused this stratum to settle.

"This can readily be determined, if indeed it has not already been done, by making borings three or more feet below the elevation of the cutting edges of the caissons. Should the borings show solid

rock, then the natural inference is that the caissons are imperfectly constructed. I would therefore suggest that a careful examination of the bed of the river be made and the character of the obstructions ascertained. Boring should then be driven to disclose the nature of the rock on bottom. This should be done very carefully; and finally the caisson or crib should be inspected to ascertain condition of timbers, etc.

"A double steel caisson of sufficient diameter and with four or five compartments could then be sunk to bed-rock, using compressed air to remove the débris between the two cylinders. When this is done the space between the inside cylinder of the steel caisson and the wooden crib can be pumped and cleaned out to bed-rock; when an inspection will disclose the best method of correcting the trouble.

"It is possible that by the use of hydraulic jacks the pier can be raised to place and the air chamber filled with Portland cement concrete. It may be necessary, however, to remove the old Louisville cement concrete from the air chamber, and substitute Portland cement concrete, as indicated above. I think that this method is about the only sure way to make an examination, be fitted for making the necessary repairs, and at the same time not interrupt the traffic on the bridge, which in itself would be quite an item of additional expense."

In that letter, Mr. Way advanced the theories that the caisson had not been landed on rock, that the cutting edges might have spread, or that the rock under the cutting edges might be only a thin layer over inferior material. He recommended sinking an annular (circular) caisson and coffer-dam around each pier and raising the pier to place by hydraulic jacks, and underpinning the piers, even to removing the old Louisville cement within the working chamber. Later, his report was followed quite closely by the late W. M. Patton,* and large expenditures were made along those lines.

After the Railway Company's forces had handled the problem for 15 years, Mr. Patton was called in as Consulting Engineer. He studied the history of the bridge and, after making borings through the timber crib and caisson under the pivot pier, within the well inside the pier, and examining the exposed portions of the crib by divers, came to the conclusion that the caissons were not founded on rock, and gave the Railway Company a full and very plausible report and recommendation, which, on account of its unusual nature, is reprinted in full in Appendix A.

* Author of "Treatise on Foundations."

Patton's Report.

In brief, Mr. Patton concluded that one corner of the cutting edge of each pier rested on rock and the remainder on inferior material, which condition, together with the eccentricity of loading, caused the settlement; that greater scour at one corner than at the others caused the greatest settlement at the corner of greatest scour. He suggested pumping grout into the underlying sand to convert it into concrete; removing the inferior material under the caisson and replacing it with concrete, and, to accomplish the latter, discussed freezing the sand to the river bed to form a frozen sand coffer-dam. He also suggested an ordinary coffer-dam, which he dismissed on account of the difficulty of getting it tight in that material and at that depth; proposed the use of a pneumatic caisson with the old crib and caisson as one of its walls, which latter he concluded to be very risky; and suggested an entirely independent annular coffer-dam, which he finally recommended. His diver found that the timbers were sound, but that some damage had occurred to the crib sheeting and timbers on account of the settling; and that the filling was of small rock, sand, and gravel. Mr. Patton recommended replacing the sheeting and filling the spaces with concrete. He also recommended the sinking of annular caissons and coffer-dams to rock, supporting the span on falsework, removing the material between the old and new piers, putting jacks under the cutting edges to right the piers, and underpinning them with concrete. As an afterthought, he suggested that the rock, under the cutting edges at the sides of the pier which had not settled, might be cut out, and those edges lowered to make the piers assume perpendicular positions. He went so far as to say that from 30 to 35 hydraulic jacks, with main cylinders $3\frac{1}{2}$ in. in diameter and plungers $\frac{3}{4}$ in. in diameter, would raise 30 tons each. It is not known how he proposed to work the jacks when under the cutting edge, as he recommended letting the annular caisson flood while jacking so as to reduce the weight to be lifted. His estimated cost was $40 000 for the coffer-dam around the pivot pier, with $4 000 for raising and leveling it, and $34 000 and $3 500, respectively, for Pier 4, a total of $81 500.

It is puzzling that Mr. Patton did not determine by simple calculation that, if Pier 4 could be righted by such a method as he suggested,

the top would be in such a position that the ends of the spans supported by it would not fit the top of the pier in the new location, as it would have been moved over 3 or 4 ft. It also appears that he ignored the statements of the contractor and resident engineer who built the piers that they were surely founded on rock. Later, the sinking of the coffer-dam around Pier 4 disclosed the fact that the rock slopes in a direction opposite to the slope on which he based his theory, a fact that could easily have been determined by running jet pipes down to rock at several places around the pier.

ANNULAR COFFER-DAMS SUNK IN 1898 AND 1899.

Mr. Patton's report was accepted, and bids were requested on his plans and specifications, with the following results:

Engineering-Contracting Company. (Charles Sooysmith, M. Am. Soc. C. E.):

Pivot pier, $38 332. $1 500 per ft. below 40 ft. below low water.

Pier 4, $36 010. $1 200 per ft. below 45 ft. below low water.

$18 per cu. yd. for work below the cutting edge of both piers.

Missouri Valley Bridge and Iron Company. (The late A. J. Tullock, M. Am. Soc. C. E.):

Pivot pier, $31 600. $800 per ft. below 40 ft.

Pier 4, $27 950. $750 per ft. below 45 ft.

Removal of material between new coffer-dam and old pier and all other work, cost plus 10 per cent.

McGee-Kahmann and Company, Kansas City:

Both piers, $116 000.

Excavation of material between, $1 per cu. yd.

Three companies made propositions for building new piers, as follows:

McGee-Kahmann and Company proposed to build four new piers, 50 ft. north of the present piers, launch a draw-span 50 ft. north, and construct a new span 50 ft. shorter between Piers 5 and 6 and a deck plate-girder at the south end, for $99 000. They also made an alternate bid to build a new draw-span, 80 ft. longer than the old one, reaching from the south abutment to the new piers, renewing Piers 2, 3, and 4, farther north, and to build a new span between Piers 4 and 5, for $125 000. The latter plan would have left in the defective Pier 5.

The Missouri Valley Bridge and Iron Company proposed to build an entirely new set of piers according to the best modern practice, for $125 000.

All propositions for new piers were rejected, and the bid of the Missouri Valley Bridge and Iron Company for going ahead on Mr. Patton's recommendation was accepted. Mr. A. J. Tullock, then Proprietor of the Missouri Valley Bridge and Iron Company, had made a careful investigation before bidding; the correspondence accompanying his bid pointed out the weaknesses of Mr. Patton's scheme, and made certain recommendations. On account of the value of Mr. Tullock's conclusions, his letters of August 17th, 18th, and 19th, 1898, to Mr. E. Fisher, then Engineer of Bridges and Buildings, of the Railway Company, are given in full in Appendix B.

As a result of his study, Mr. Tullock raised a doubt as to the correctness of the theories formerly advanced regarding the trouble, and attributed it to the crushing of the crib timbers. He pointed out the impracticability and probable impossibility of carrying out the Patton scheme, and recommended against it, giving as his opinion that it was too dangerous to warrant its adoption. He recommended that the cribs be cleaned out and filled with concrete. Although recommending against the repair work, he submitted the lowest bid for it, and received the award.

The work of sinking the annular caissons and coffer-dams went forward in the fall of 1898, and was completed early in the summer of 1899.

At Pier 4, a timber caisson, about 50 by 70 ft., was constructed around the old pier, the intention being to carry out the work, as nearly as practicable, in accordance with Mr. Tullock's proposal of August 17th, 1898 (Case 2, Appendix B).

Two rows of piling were driven around the old pier, about 8 or 10 ft. apart, and were capped and cross-capped; the caisson and crib were built on top of these caps to a height of 12 ft. Large screws, 16 ft. long, were then used to lower the crib until it floated. The crib projected 4 ft. above the water, and the cutting edge floated about 4 ft. above the bed of the river; sand was used to fill the crib to sink it, while men were raising timber on top of the crib.

On March 1st, 1899, with the cutting edge on the bed of the river at an elevation of 11 ft. below zero, air was forced into the working chamber and excavation was made through the following material:

From Elevation 11 to 17.....Sand.
From Elevation 17 to 23.....Rip-rap and sand.
From Elevation 23 to 41.....Sand.

On April 2d, 1899, at 41 ft. below low water, hard shale was struck near the center of the up-stream end. From 41 to 45 ft. below zero, excavation was made through very hard black shale on the north side and at the up- and down-stream ends. This rock was nearly as hard as granite, requiring dynamite to make the excavation.

At an elevation of 45 ft., the inside cutting edge on the south side was landed on rock, except about 10 ft., where the rock was 6 in. below the edge. The rock under the outside cutting edge on the south side was from 12 to 13 in. below it. However, the sand was taken out down to the rock, and the working chamber was sealed with from 2 to 4 ft. of concrete, depending on the depth of rock.

The crib was built 58 ft. high, the top being 13 ft. above low water when the caisson was sealed. Later, the top of the crib was disconnected, from 6 to 7 ft. below low water, after concrete had been placed between the old and new cribs. The sealing of the working chamber was completed on April 24th, 1899.

The river began rising very rapidly on April 22d, and on the 23d a 7-ft. rise was reported at Fort Smith. This reached Little Rock a few hours after the work of sealing the working chamber had been completed, the water rising over the top of the crib. Work was suspended from April 25th until June 30th, and then two pumps and an air-lift were used to remove the water between the old and new cribs, and men commenced excavating the loose sand and sediment from around the old pier, but no effort was made to go below the depth uncovered by the pumps, or to remove the silt. The silt and sand were cleaned out to a depth of 5 ft. on the up-stream and 7 ft. on the down-stream end below the top of the old crib. Investigation of the timber in the old crib disclosed crushing on the north side, but only to the extent of compressing the timber, and not dividing the grain. The timber was good and sound.

A great deal of the 3-in. sheeting was found to be torn off, and it was seen that the spaces between the timbers of the crib were filled with sand and loose rock. The sheeting which had been torn off was replaced. It was also observed that the deck or top of the old crib dipped from 1 in. to 1½ in. from a point near the center on the south side of the pier toward the up-stream end.

On July 1st, while the loose material between the new coffer-dam and the old crib was being excavated, it was discovered that the pier had settled about ½ in. This led to the immediate abandonment of the excavation, but the spaces on the north and west sides were driven full of piles, with a penetration of about 15 ft., and the space already excavated was filled with concrete up to the top of the old crib. None of the material within the old crib was removed, and no effort was made to grout it or to fill in the vacant spaces with concrete. In fact, the sheeting that was replaced effectually prevented the concrete from flowing into the vacant spaces within the crib. The concreting around the old pier was completed on July 6th, 1899, and both walls of the annular coffer-dam were then removed, down to 6 or 7 ft. below low water.

The location of the new annular caisson and coffer-dam around Pier 4, with reference to the old crib, together with the general construction of both, is shown by Fig. 5, which also shows in cross-section the concrete, from 3 to 5 ft. thick, that was placed between the old crib and the new coffer-dam. The annular caisson was about 50 ft. wide and 70 ft. long, the sides were 10 ft. apart, and spaces from 6 ft. to 7 ft. 6 in. wide were left between the old and new work.

The work at the pivot pier was similar in character, except that the new caisson was 70 ft. square and the concrete about 15 ft. thick, the extra depth having been caused by scour and not by excavation. (Fig. 5 does not show correctly the pier top at this time (1898), but as it appeared several years later, after additional movement had taken place.)

Mr. Tullock considered the removal of the material between the new and old caissons to be very hazardous, and he continued to impress this opinion on the officials of the Railway Company. He was so much impressed by it that he continually recommended and urged that only part of the material be removed and that the remainder be confined by placing concrete over it. Unfortunately, the Railway Com-

pany was guided by his advice in this matter. Two of Mr. Tullock's letters to Mr. Fisher, relative to this matter, dated November 24th, 1898, and May 16th, 1899, are printed in full in Appendix C.

It is to be regretted that, after having incurred the great expense of sinking the annular caissons, more benefit was not derived from them. The scheme of jacking up the piers and underpinning them

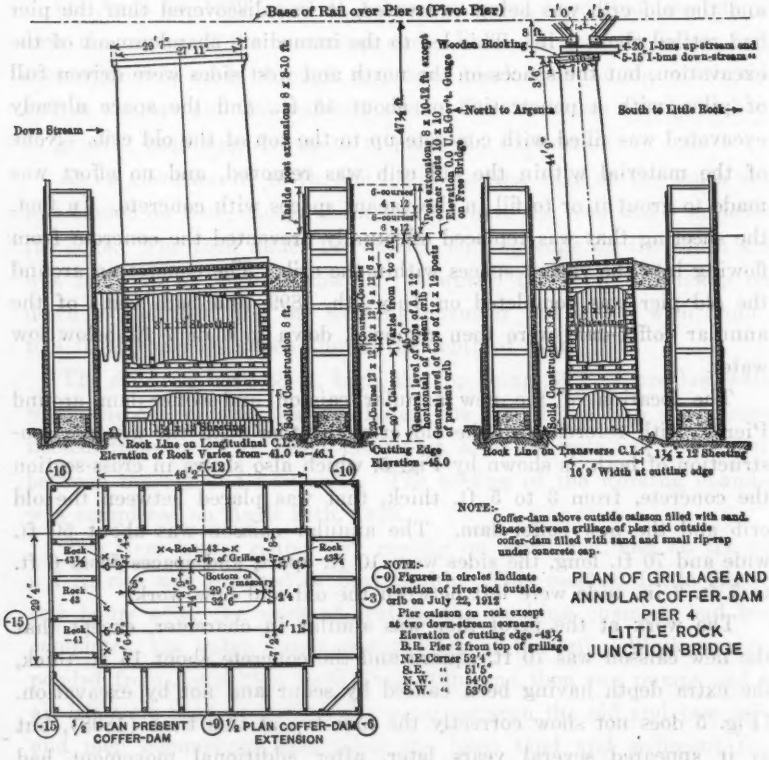

FIG. 5.

appears to have been abandoned early, as no reference to these matters can be found in the files during the work. Neither was any effort made, by exploring under the cutting edges of the new caissons, to determine the depth to which the original caissons had been sunk.

During May, 1899, the concrete having been placed around the pivot pier, the wheel-tread under the drum of the draw-span was leveled up

and underpinned with concrete, the minimum rise being 2⅜ in. and the maximum 6½ in.

At the same time, but prior to the placing of the concrete around Pier 4, the spans on that pier were also leveled up and carried on oak blocking in place of the bed-plates, the spans being raised from 1¼ to 6 in. This work was done too soon, as a slight settlement of Pier 4 during the work threw the track out of line.

The pier tops had moved around so much, and their upper surfaces were so small, that the trusses could not be placed on a straight line. The trusses had been built with extra wide clearance to provide for highway traffic, and this permitted considerable latitude in the location of the track. The trusses were permitted to remain out of line, and the track was placed on a tangent, being nearer to one truss than to the other where the spans were out of line. The location of the center line of the track with reference to the track stringers and trusses is shown on Plate XXXII.

Further Movement of Pier 4.

On account of the large quantity of concrete placed around the pivot pier, and the depth to which it reached, 15 ft. below the top of the crib, no further movement has been detected in this pier. However, the movement of Pier 4 was not arrested, but as the settlement and movement continued, a policy of "watchful waiting" was followed for several years. The situation again became critical early in 1906, when Pier 4 had moved so far that one of the spans was in imminent danger of falling off.

At that time J. C. Bland, M. Am. Soc. C. E., was retained as Consulting Bridge Engineer of the Missouri Pacific Railway, and was asked to look into the matter and pass on it. He arranged to have John N. Ostrom, M. Am. Soc. C. E., to visit the bridge and report on it. That portion of Mr. Ostrom's report having reference to the foundations is as follows:

"The roller nests at north end of span, which is next to the draw-span on the north, are badly shifted to the south, so that two of the rollers do not bear.

"The main trouble with the bridge is in the foundations, and, like the Baring Cross Bridge, about one mile above, there are no original records showing the exact conditions of the bearings on the bottom.

The pivot pier, Pier 3 and Pier 4, on the north side of the pivot, are all tilted up stream and also sideways.

"The pivot pier and Pier 4 have been protected by concrete additions extending clear around the base on the outside and reaching down into the rock. It is believed that the tilting of the pivot pier, at least, has been arrested.

"The piers also have well-defined vertical cracks extending through several courses, indicating uneven bearing on the bottom, but the cracks are not bad enough to endanger the structure at present.

"The south abutment has a deep crack in the up-stream wing-wall, and the north face next to the river has several bands, one above the other, held by bolts which pass south into the abutment.

"Pier 7 on the north shore is cracked, and banded with tie-rods running through yokes on the up- and down-stream ends.

"The most important matter at present is to make careful measurements at least once a month on all the piers and abutments with a view of determining whether or not the tilting and cracking has stopped. If these measurements show that the masonry has become fixed in position, it may be assumed safe for the life of the present superstructure, but it would not be suitable for a new bridge designed under present specifications.

"If the cracks in piers increase, they should be banded, and the cracks should be pointed as soon as practicable, to exclude water.

"Owing to the tilting of foundations, the surface and alignment of the track is very bad on the bridge. As the piers have tilted up stream the track has been shifted down stream to keep the alignment as good as possible until the down-stream stringers are carrying considerable more than half the load. Furthermore, the clearance between the train and the down-stream truss has been reduced by the amount of shifting of the track."

"JNO. N. OSTROM."

"To MR. J. C. BLAND.

"MAY 21, 1906."

In transmitting Mr. Ostrom's report to M. L. Byers, M. Am. Soc. C. E., then Chief Engineer of Maintenance of Way, Mr. Bland wrote in part as follows:

"JUNE 4, 1906.

"M. L. BYERS.

"One can hardly tell much about the masonry tilting. The plans you sent show the tilting but do not say the character of foundation, nor whether the condition is becoming worse. You will notice that Mr. Ostrom says:

"'It is believed that the tilting of the pivot pier, at least, has been arrested.'

"Who is it that says so, and on what grounds?

"I think you should use slow speed over the bridge, and also I would prohibit the stopping and starting of trains on bridge, if such an order is practicable.

"J. C. BLAND."

Following this report no immediate action was taken.

One of the first duties assigned to the writer when he entered the Bridge Department of the Railway Company, late in 1907, was an inspection of this bridge in order to determine how to maintain it in safe condition. At that time, the location of the pedestals of the spans with reference to the coping courses on Piers 3, 4, 5, and 6, was as shown in Fig. 6. Pier 4 had moved out so far from under the shoes that the center of the end pins was almost exactly over the edge of the timber blocking under the shoe; the edge of the shoe overhung the edge of the pier, as shown in Fig. 7.

PLAN SHOWING RELATIVE POSITIONS OF
TRUSS PEDESTALS AND TOP OF PIERS
LITTLE ROCK JUNCTION BRIDGE
DEC. 1907

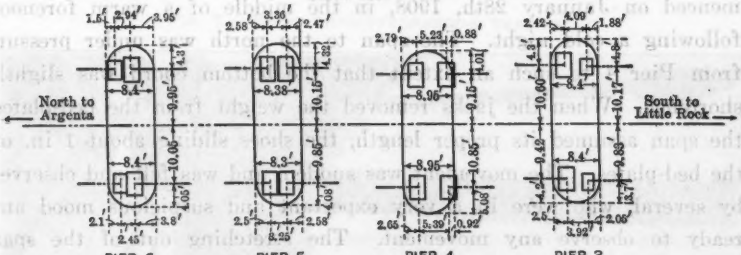

FIG. 6.

The roller end of the span to the south being on Pier 4 permitted the pier to move out from under. The fixed end of the span to the north being on Pier 4, the thrust caused by the leaning of the pier in that direction had crowded the roller end of this span on Pier 5 hard against the fixed end of the next span. This thrust, added to the similar, though less, defective construction of Pier 5, caused the latter to lean north, crowding the roller end of the next span to the north, hard against the fixed end of the north span on Pier 6, bringing three spans in hard contact. On hot days, when the bridge was not loaded, the chord bars in the end panels of these spans could be seen to be more or less buckled, but they always straightened out

under trains, undoubtedly because the elasticity of the timber cribs permitted the piers to move back and forth.

Immediately following his first visit to the bridge, the writer worked up plans for placing a nest of I-beams under the truss shoes at each end of Pier 4, so that the overhanging ends of these beams would afford support for the end of the next span south to keep that span in the air instead of in the water. Fig. 9 shows the arrangement of I-beams for this purpose. There was only sufficient depth for 15-in. I-beams at the high end of the pier, but at the low end, there was sufficient depth for 20-in. beams, the difference in height being due to the settlement.

The plans first contemplated driving piles on both sides of Pier 4 to be used for jacking during the placing of the I-beams, but, on account of the extreme length of the piles required (from 80 to 90 ft.) and the hazard attending their maintenance in the Arkansas River, it was decided to avoid their use and jack from the pier top.

The jacking arrangement was set in place and jacking was commenced on January 28th, 1908, in the middle of a warm forenoon following a cold night. The span to the north was under pressure from Pier 4 to such an extent that the bottom chord was slightly shortened. When the jacks removed the weight from the bed-plates, the span assumed its proper length, the shoes sliding about 1 in. on the bed-plates. The movement was sudden, and was felt and observed by several, who were in a very expectant and suspicious mood and ready to observe any movement. The stretching out of the span was overlooked, as it was not noticed immediately that no corresponding movement had taken place under the roller end of the other span on the same pier. The pier had such a bad record that all the men engaged on the work believed it had suddenly moved and was going to fall, and the forces, led by the foreman, fled from the structure, headquarters being advised by telegram as follows:

"Began jacking bridge this A. M.; raised 1 in. when Pier 4 moved north 1 in. Will be necessary to yoke Piers 3 and 4 to span before it will be safe to handle driver for falsework. It will be necessary to put spans on falsework before can resume traffic."

As an emergency matter, to retard the movement of Pier 4 and to avoid any such scare during the work, the yokes and rods shown

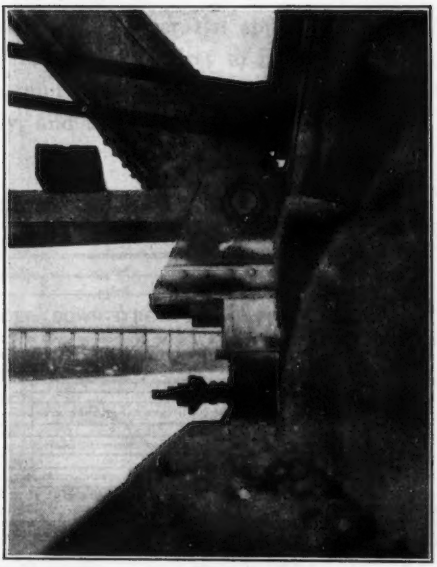

FIG. 7.—TRUSS SHOE OVERHANGING BEARING.

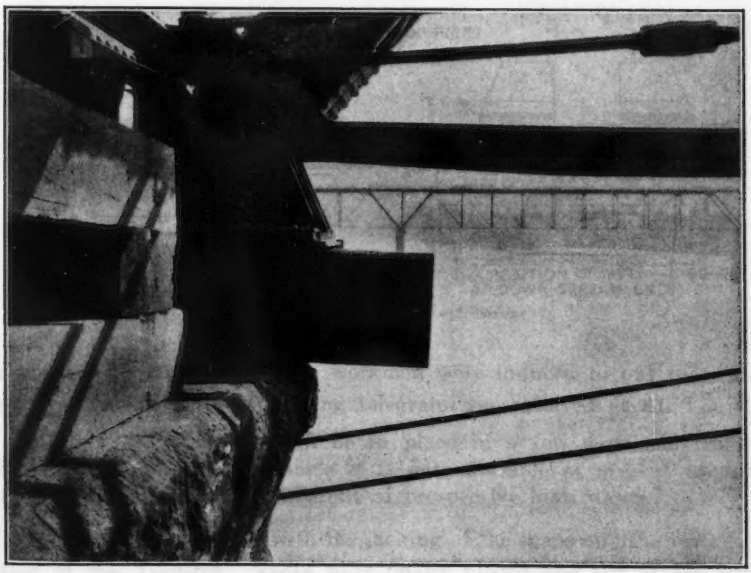

FIG. 8.—TRUSS SHOE ON I-BEAM GRILLAGE.

by Fig. 10 had been designed, but the conclusion was reached that they would not be necessary. After the apparent movement of the pier, however, it was impossible at first to induce the workmen to return to the structure, and arrangements were completed to make the rods, etc., immediately, and to apply them—for their moral effect as much

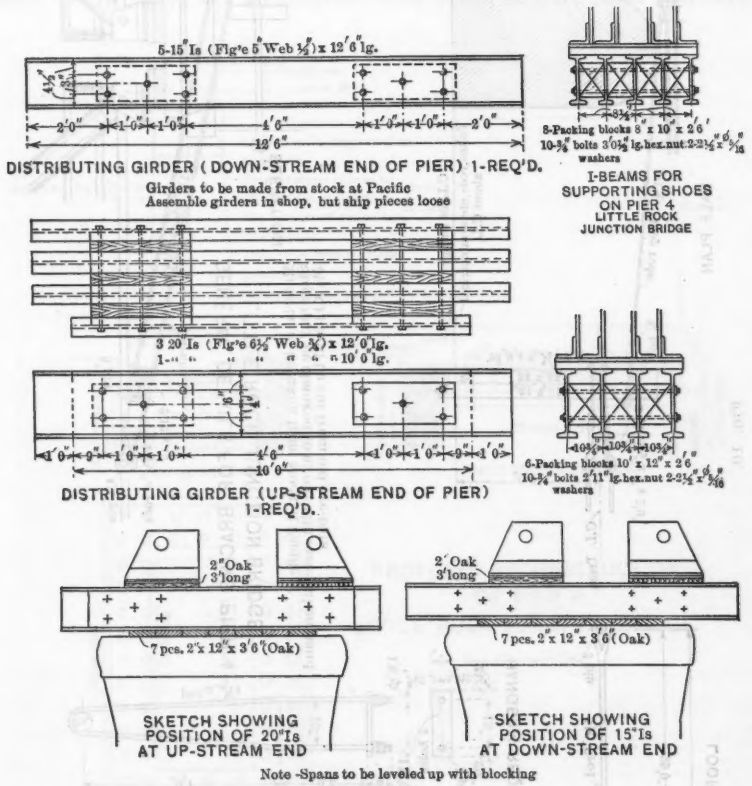

FIG. 9.

as for any other reason. The workmen were induced to put them in place, after which the following telegram was received at St. Louis:

"Yokes and I-beams will be in place in a few days and traffic then can be resumed. Believe it is not advisable at present to put falsework under spans on account of prospective high water."

They then went ahead with the jacking of the spans and the installation of the I-beams. These were finally placed and the bridge was

every month. No further attention was paid to the placing of the falsework. The condition of the bearing under the expansion end of the span to the south, before the I-beams were placed, is shown by Fig. 7. Fig. 8 shows the condition afterward. The bearing having been made safe, the matter of permanent repairs was then given further study.

Plans for Reconstruction of Pier 4.

Late in 1907 tentative plans had been made to replace Pier 4 by a larger one. It was planned to place the two spans resting on Pier 4 on falsework, take down the masonry pier to the top of the crib, drive as many piles as possible in the annular space between the old crib and the 1898 coffer-dam, construct a grillage of beams in concrete over the old crib and new piles, and build a new pier on top of this. The work was estimated to cost about $40 000, not including falsework materials, work-train service, etc., to be furnished by the Railway Company, and other incidentals which would bring the cost up to from $50 000 to $60 000. Fig. 11 is the plan, prepared at that time by the Engineering Department of the Railway Company, after con-

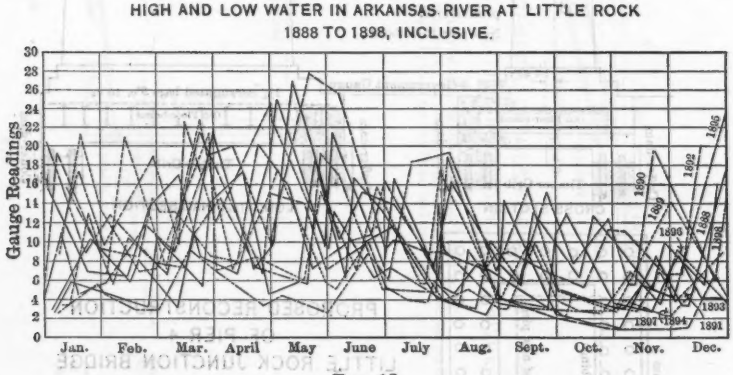

Fig. 12.

ference with the Superintendent for the Contractors who had sunk the 1898 caissons. It was approved by Mr. Bland, who stated that the work should be carried out at the earliest possible date. The writer objected vigorously to carrying out this plan at that time, for the following reasons.

1.—Difficulty of Maintaining Falsework in the Arkansas River.—Figs. 12 and 13 are hydrographs of the Arkansas River for 20 years, 1888 to 1908, and show that in the spring, when it would have been necessary to maintain two 253 ft. 4-in. spans on falsework with 80-ft. piles in the middle of the river, the floods are greatest. They also show that sudden rises can be expected in any month of the year, and are greatest in spring and least in early fall. Rises in the Arkansas are invariably rapid, and are characterized by excessive

quantities of drift, some of it whole trees, 80 or 90 ft. long, from 2 to 3 ft. in diameter and full of branches, and also by deep and rapid scour, down to rock, of the fine sand and silt forming the bed, especially around obstructions of any nature. In the past the Arkansas has taken heavy toll in falsework and spans, and there is hardly a bridge across the river where there has not been some trouble from this source. It is practically certain that great loss would have been suffered had the spans been put on falsework at that time, and the danger would have been increased by the delays in rebuilding the pier, which could be expected from the spring floods. In fact, this consideration has influenced the writer, in the handling of this bridge up to date, to the extent that piles have never been driven for falsework purposes in the repairs that have been made.

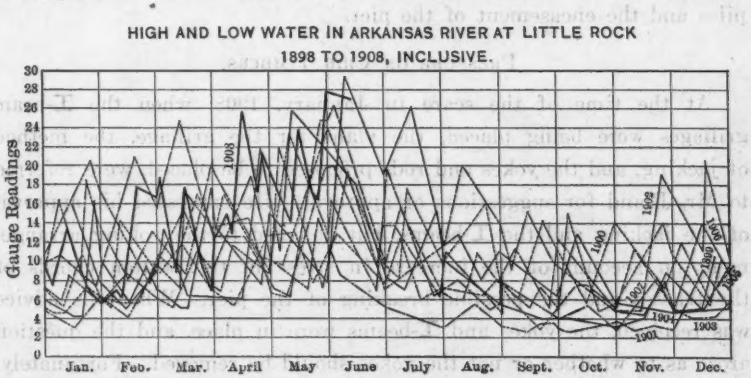

FIG. 13.

2.—No Provision for Strengthening the Weak Crib.—The plan did not provide for any correction of the weak crib, and it would have been impossible to calculate the distribution of load, as between the very compressible crib and the rigid pile foundation, which would have surrounded it. It was practically certain that from the very first the proposed piles surrounding the crib would be badly overloaded, and failure of some sort could be expected. In fact, the proposed pier was so much larger than the old pier that, if the load could have been distributed uniformly over the base, the weak crib would have been required to carry more load than before.

3.—Better results could have been obtained at greatly reduced expense by driving piles as proposed and building up on them a

reinforced concrete shell enclosing the old pier, thereby saving the latter and avoiding the cost of its renewal, all the cost and hazard of falsework, and, to a great extent, the uncertainty as to the distribution of the loading. The art is sufficiently advanced to insure absolutely efficient bond between the new encasement and the old masonry (the old was rough rock-face). The reduced uncertainty as to the distribution of the load is due to the fact that from the first the crib would carry its maximum load and be fully compressed during the construction of the encasement, so that the new support would work well with the old.

These three reasons were sufficiently potent to prevent the adoption of this scheme, but it was not possible for the writer to secure in the near future authority to go ahead with the driving of additional piles and the encasement of the pier.

Pressure on Crib Timbers.

At the time of the scare in January, 1908, when the I-beam grillages were being placed, the plans for the grillage, the method of jacking, and the yokes and rods proposed to be placed, were referred to Mr. Bland for suggestions or approval. He expressed his approval of the jacking and the I-beams, but objected to the yoking arrangement on account of the increase in stress in the bottom chords of the trusses and the possible breaking of the pier. When his advice was received, the yokes and I-beams were in place, and the question arose as to whether or not the yokes should be removed. Fortunately, no one was prepared immediately to assume the responsibility of removing them, and as the writer had suggested putting them on, he was requested to show cause why they should be permitted to remain. Rough figures had previously been prepared, showing the pressure on the crib timbers and the effect of the yokes, but to show better the beneficial effect of even a moderate pull near the top of the pier, the lines and intensities of pressure were determined for all probable conditions of loading and assumed stresses in the yokes. Plate XXXIII shows the results, and indicates that even a moderate pull at the top of the pier would be of considerable advantage. The nuts were tightened from time to time, and the springs were kept at such a pressure as to maintain a pull of about 50 000 lb. As the end panels of the bottom chords of the trusses had 48 sq. in.

UNDER

DIFFERENT CONDITIONS OF LOADING

UNIV. OF MICH.

of cross-section, figures of 48 000 and 96 000 lb. were assumed in the calculations, for the amounts of pull corresponding to 1 000 and 2 000 lb. per sq. in., respectively, the latter figure having also been used in the calculations to ascertain the results if the pull should reach double the amount assumed. The results showed conclusively that the trusses and the masonry pier were not adversely affected by the pull of the rods. The maximum stress in the bottom chord under the heaviest loading was about 13 000 lb. per sq. in. before the application of the rods and about 15 000 lb. per sq. in. afterward, an amount well within safe limits.

In order to avoid damage to the pier by the concentration of the pull of the yokes, bearing timbers had been cut to fit the shape of the rock face of the pier and placed in contact with the pier for a height of about 10 ft., resulting in spreading the greater part of the pull over four or five courses.

Fig. 10 shows the yokes and rods. The arrangement consisted of three 8 by 16-in. timbers laid horizontally and blocked against the side of the pier toward which it was leaning, the ends projecting beyond the pier ends and being attached at each end to two 1¼-in. round rods with upset ends. The rods passed close by the pier and extended up to the first panel points of the trusses, where, by the timbers and U-rods, the pull was transmitted to the bottom chord of the trusses. Heavy car springs were introduced at points of bearing partly to take up the expansion and contraction. The other end of the span to which the yoke had been connected was attached to Pier 3 by a duplicate of this arrangement.

The line of pressure is well within the middle-third for all cases except when the south span only is fully loaded, under which condition the line is outside the middle-third for the top 20 ft. The compression on one side and the tension on the other side did not reach intensities that would cause any alarm, however, and the effect of the pull on the rods was only barely appreciable at that section of the pier.

Alarm had been felt, and the opinion was freely ventured, that the pier was held standing by the weight of the trusses. To dispel this alarm, Case I was chosen; as might have been expected, it shows the fallacy of that opinion and the entire safety of the pier when standing alone.

The records indicated that the crib timbers were 2 ft. 6 in. apart, the old plans showing six longitudinal and thirteen transverse timbers in alternate courses, the bearing areas being the intersections shown cross-hatched in Plate XXXIII, a total of 78. The timbers were assumed to be 12 in. wide, thus giving a bearing area of 78 sq. ft. The diagrams showing the distribution of pressure on the timbers of the crib were prepared on this basis, on the assumption that the timbers carried the entire load, and the intensities that have been crossed out were the result. Several years later, when the crib was uncovered, it was learned that there were only five longitudinal and eleven transverse timbers in the alternate courses, and that the center intersection had been omitted in order to make room for the shaft, giving 54 intersections instead of 78. The timbers were found to be of various sizes, from 11 to 12 in. wide, so that the total bearing area was in reality about 50 sq. ft. It was also learned that the timbers carried practically all the load. Calculation with reference to the true conditions would have increased their intensity about 60%, or to the figures given above those crossed out. The maximum pressure of 555 lb. per sq. in. on one side, with 17 lb. per sq. in. on the other, calculated from the information available when the study was first made, easily accounted to the writer for the uneven settlement of the pier, but he had few adherents. Had the correct figure of about 888 lb. per sq. in. in cross-bearing been available at that time, all might have been convinced.

The position of the cross-section of the pier above the crib in Plate XXXIII was plotted from very careful measurements in 1908 from the plumb-line shown at the left. The position of the crib and caisson, shown in full lines, was estimated on the assumption that the tilt of the pier was caused by the crushing of the timbers uniformly distributed throughout the height.

The position which the crib and caisson would have occupied, on Mr. Patton's theory of settlement into the foundation and no uneven crushing of timbers, was found by projecting the sides of the crib at right angles to the top, the location and slope of which had been measured. The right-hand cutting edge of the caisson would have been at *C*, and if, by jacking under the other edge, the pier had been revolved about *C* to plumb position, it would have reached the position shown by the dotted lines. The absurdity of that theory is indi-

cated by the position the top of the pier would have occupied with reference to the pedestals of the trusses. The span to the right was never any farther to the right, its position being controlled by its proximity to the draw-span and the proximity of the latter to the south abutment. There would not have been room for the south pedestal of the next span to the north, shown at the left on Plate XXXIII.

The figures shown on Plate XXXIII convinced all concerned that there would be no danger in permitting the yokes to remain in place, and orders were issued to keep them tight. No fear was felt as to the effect of the pull on Pier 3, at the other end of the span, to which the yokes had been applied, because the south side of that pier had been built plumb, the entire batter being on the north side, the natural lean of the center of the pier being opposed to the direction of pull; in fact, the pull really improved the distribution of stress in Pier 3 in a manner somewhat similar to that at Pier 4, but less pronounced.

Fig. 3 shows Pier 4 after the yokes and I-beams had been applied, and on Fig. 14 there are transverse and longitudinal sections through the pier showing the relations between the yokes, the I-beams, and the pier.

Steel Bent Constructed at Pier 4.

In 1908, some one got the idea that it would be of advantage to provide further rigid support for the overhanging ends of the I-beams on the high side of the pier by building a concrete footing on the wide edge of the crib up to low water and placing a steel bent on top of that footing, as shown by Fig. 15. The I-beams under the pedestals were to be shifted far enough south to get bearing on the bent, and the spans were to be shifted as far south as possible in order to bring the load over toward the high side of the crib. This method might have been very effective had it been possible to move the spans any great distance, but, on account of the proximity of the south span to the draw, and of the north end of the north span to the edge of Pier 5, only a 6 to 10-in. movement could be made, and the effect on the line of pressure was barely perceptible. However, the work was done in the fall of 1908, by the Missouri Valley Bridge and Iron Company, at a cost of about $2 000. Fig. 16 gives a general idea of the manner in which the work was carried out.

Holes were drilled in the top of the crib and in the side of the pier at low water, and bent reinforcing rods were placed in them. A form

FIG. 15.

umns were then encased in concrete up to high water, and a reinforced concrete shell was constructed between them to ward off drift.

Then the I-beams and spans were shifted as far as possible, in order to throw the greatest possible load on the new bent. The work was carried out carefully and expeditiously, and offered no unusual

difficulties. Fig. 17 is an end view of Pier 4, showing the new bent in place.

Following this work, no appreciable movement in the direction of the bridge was apparent for several months, but the movement at

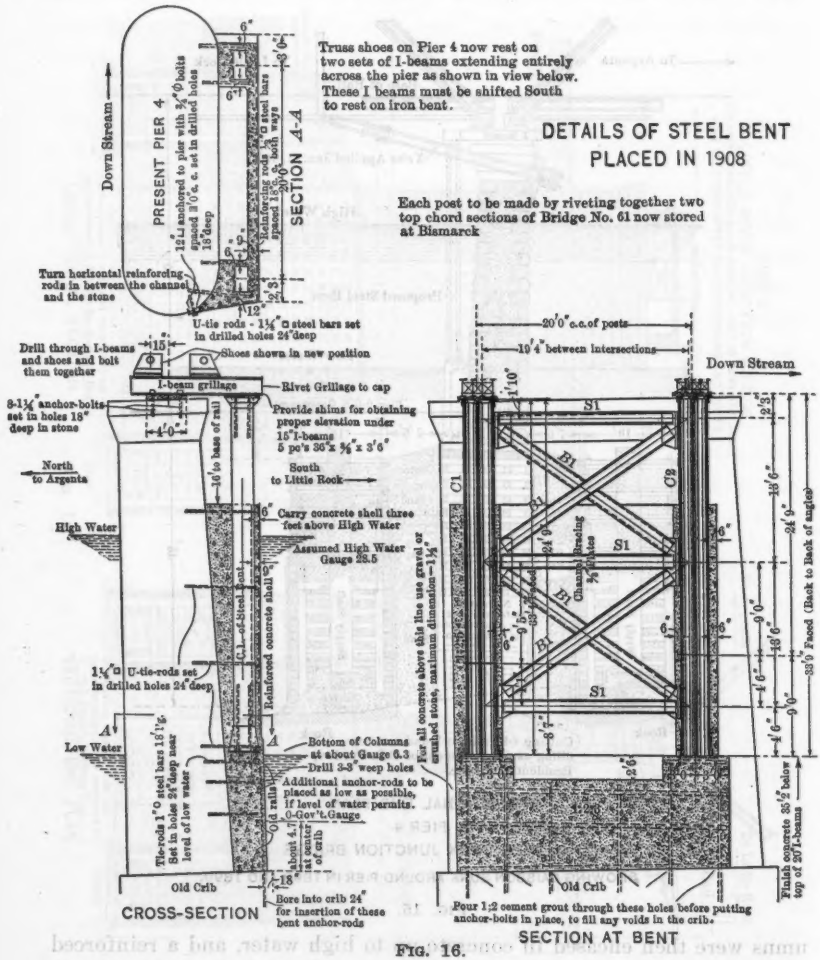

FIG. 16.

right angles to the bridge appeared to increase its rate, indicating that the work had no appreciable effect.

The movement of the pier was greatly dependent on the scour line. When the current shifted away from the pier, the bed of the

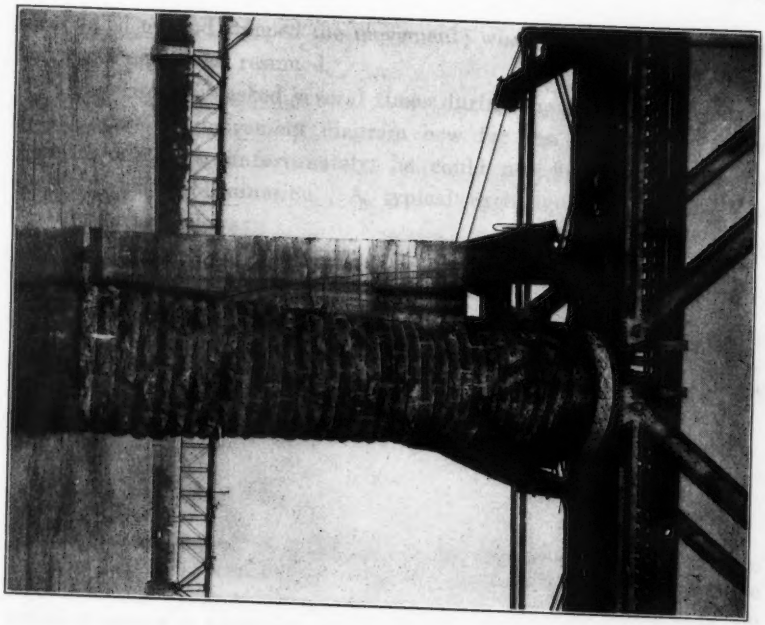

FIG. 17.—PIER 4, SHOWING STEEL BENT ENCASED IN CONCRETE.

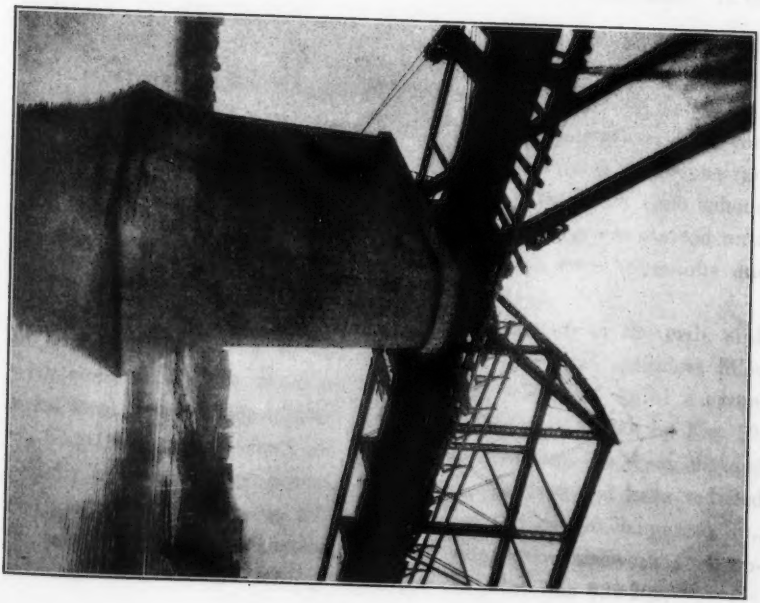

FIG. 18.—PIER 3 AFTER WORK WAS COMPLETED.

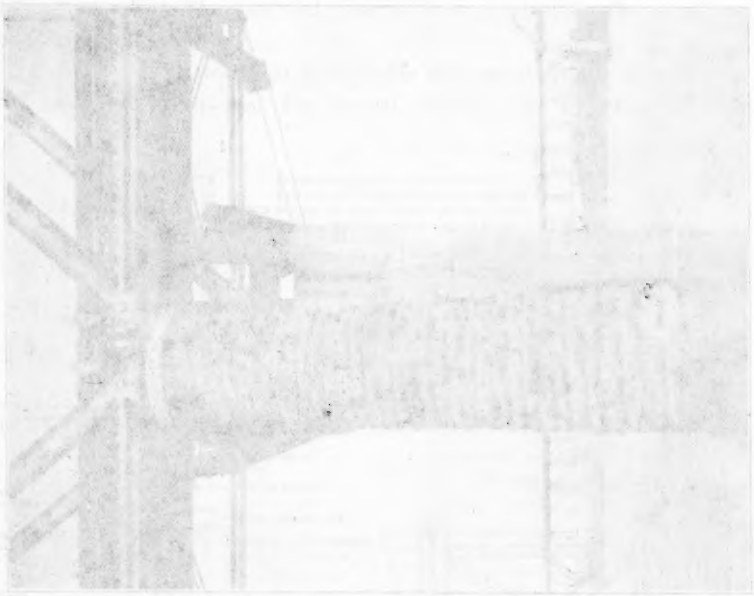

river filled up and stopped the movement; when the opposite was true, the movement was resumed.

The writer was asked several times during the next year or two to indicate on the movement diagram how far the pier could go and remain safe, but, unfortunately, he could not find any method of making that determination. A typical exchange of notes on that feature is as follows:

"ST. LOUIS, August 7, 1909.

"MR. HALE:

"I presume you are in touch with the movement records which Mr. Ford is keeping, and would like to have your opinion as to how far it is permissible to permit these movements to continue before taking further action.

"M. L. BYERS."

"8-17-09.

"MR. HALE:

"Movement record is attached. It is impossible for any one to say how far it is permissible to permit these movements to continue before taking further action. If the pier continues stationary no action whatever is necessary, as the piers are all perfectly safe. If the movement resumes we must take action.

"C. E. SMITH."

OTHER PLANS FOR OVERCOMING TROUBLE AT PIER 4.

Following the work in the fall of 1908, the observations were continued, and the matter of proposed permanent repairs or reconstruction was kept constantly alive for 3 years, during which time scheme after scheme was evolved and considered, but nothing was started until the fall of 1911. As a number of the schemes were ingenious and interesting, some of them will be described.

It was proposed to take down Pier 4 to the top of the crib, sink to rock along each side of the crib 12 or 15-in. steel cylinders filled with concrete, by the usual well-drilling methods, and build a structural steel tower on top of the cylinders and crib, as shown by Fig. 19. This was first studied on the basis of having the load divided equally between the cylinders and the crib, which would have reduced the maximum pressure on the timbers from 555 to 150 lb. per sq. in., on which basis the estimated cost, including the falsework for supporting the spans and taking down the old pier, was $32 200.

It was realized, however, that on account of the great stiffness of the cylinders and the steel tower, and the great elasticity of the crib, it would be impossible to control the distribution of load among the supports, and, in any event, most of the load would go to the cylinders. If the cylinders were made large and numerous enough and the steel tower strong enough to carry the entire load, the cost was estimated at $43 200.

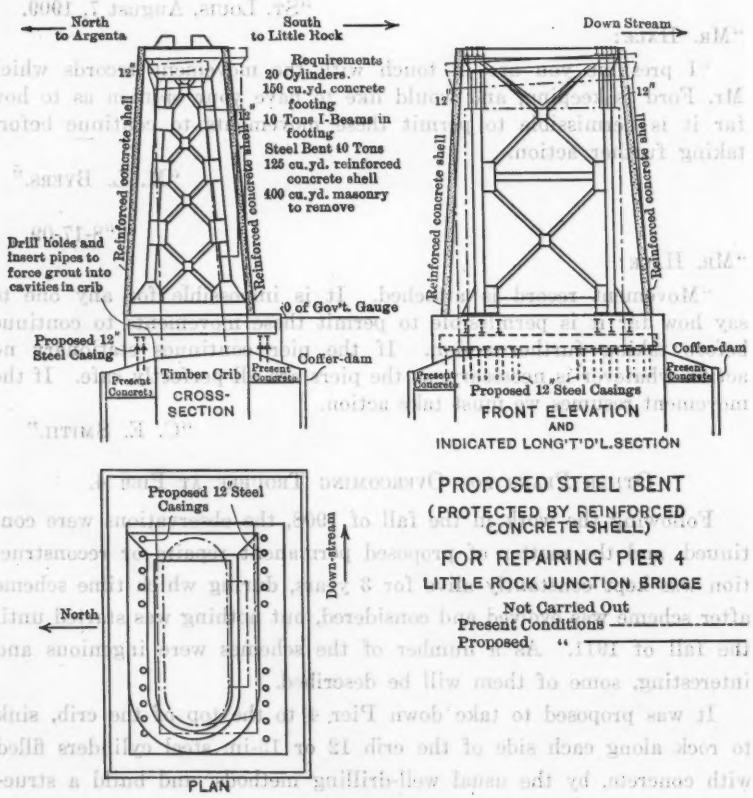

FIG. 19.

On account of the high cost and the uncertainties attendant on this scheme, it was abandoned.

The success obtained in placing the steel bent on the south side of the pier, and the small expense incurred, encouraged the proposition of building another steel bent on the north side. As there was no

projection of the timber crib on which to rest such a bent, and as the north edge was badly overloaded and thought to be crushing, it was proposed to sink a row of steel cylinders on the north side on which to rest the bent. This scheme also necessitated the use of longer and heavier beams on top of the pier, in order to distribute the load out to the bents. On account of the pedestals of the trusses being so far on the pier, it was almost impossible to study out any plan that would reduce the load on the pier an assumed amount, but, by changing the point of contact between the I-beams and the top of the pier, it was found possible to throw about 250 000 lb. on the new bent, thereby reducing the maximum pressure on the timbers from 555 to 477 lb. per sq. in. This was estimated to cost about $10 000. The scheme was abandoned on account of its uncertainty.

Of course, it would have been possible to have taken the weight entirely off the old pier and provide cross-girders sufficiently strong to throw the entire load on the steel bent, but the extra expense and uncertainties of this scheme ruled it out.

In the meantime the writer had worked up the plan shown on Fig. 20, which contemplated driving piles to rock by jetting, within two sides of the annular space between the crib and the coffer-dam, toward which the pier was moving, the plan being to remove the concrete cap a section at a time, drive several piles, and replace the concrete as a sub-footing course, and incidentally to preserve the side support afforded by the concrete. To accomplish this it was proposed to build a puddle coffer-dam around the pier within the 1898 coffer-dam in order to hold the water out against about a 10-ft. head, and to force as much concrete and grout as possible into the crib.

After grouting the crib, driving the piles, and restoring the concrete cap, it was proposed to construct, around the old pier and on top of the projections of the crib and on the new piles, a solid reinforced concrete structure which would materially enlarge the base, restore the symmetry, and effectually protect the masonry for all future time.

The rough rock-face and round ends of the pier made it particularly suited to encasement, but, in order to make the bond as intimate as possible, it was planned to drill through the body of the pier at several places near the bottom and place second-hand eye-bars through the pier, with suitable anchors at each end to be embedded in the con-

crete shell; also to curve the horizontal reinforcing rods continuously around the ends of the pier, and to replace the top by a new thick reinforced concrete cap. This plan had the advantage that no false-work would have been necessary, and it could have been carried out for $12 000.

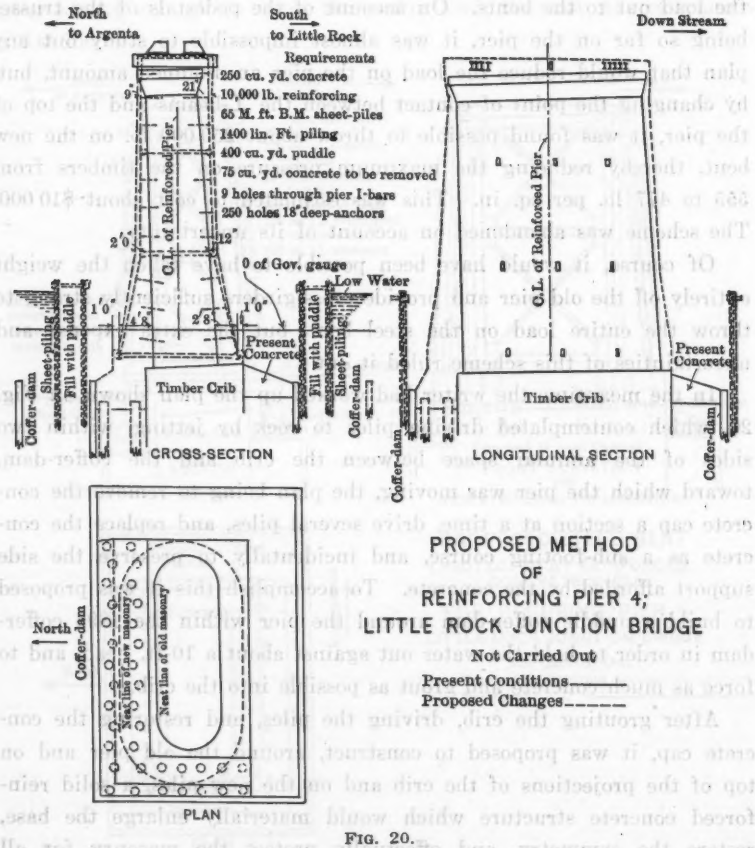

FIG. 20.

The writer has always felt that this method of repairing Pier 4 was the best that could have been devised, but so many objections were raised, as to the difficulty of extending the old coffer-dam up to make it water-tight, the danger to the pier of removing the concrete cap placed in 1899, the difficulty of driving the piles, and the possible damage to the pier by the adjacent pile-driving, the danger of

boring holes in the old crib for grouting (and possibly letting the sand run out), the impossibility of getting proper bond between the new and old work under traffic, the danger of disturbing any of the former conditions without carrying the spans on falsework, etc., *ad infinitum*, that the scheme was dropped.

Proposed Falsework for Supporting Spans.

Strange to say, several engineers who apprehended that if any work were done on the pier it would fall down, and desired the spans placed on falsework to save the steel spans in case of the collapse of the pier, proposed to support the spans in such a way that if the pier did fall it would knock the supports out from under at least one span and cause that to fall. When the writer pointed out this condition, he was requested to arrange for such temporary support of the spans resting on Pier 4 as would hold them up in case the pier should fall, the idea being to have plans for such temporary supports thoroughly understood by and in the hands of all concerned, with authority for the division forces of the Railway Company to erect the supports immediately on the further rapid movement of Pier 4.

FALSEWORK FOR SUPPORTING TWO SPANS OF LITTLE ROCK JUNCTION BRIDGE CONTEMPLATING THE REMOVAL OF PIER 4

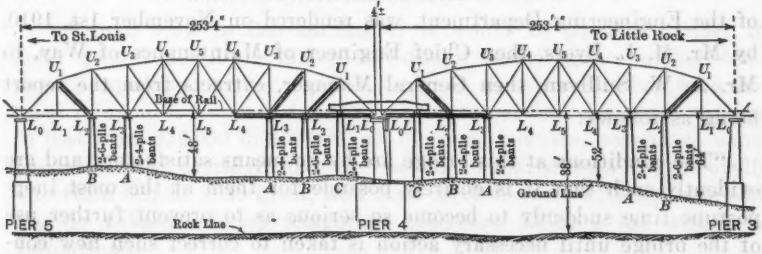

Fig. 21.

Fig. 21 shows the general plan that was worked up. On account of the necessity for retaining the greatest possible clear waterway, and the impossibility of maintaining any longitudinal bracing below high water except with disastrous results, it was proposed to place five double bents under each span, and to bridge over the pier with through girders, from which the floors would be hung. In the event of the unexpected happening at Pier 4, it was proposed to erect bents, *A*, under the third panel point on each side of Pier 4 and stiffen the tension members in the ends of the trusses so as to enable them to

resist the compression that would result if the pier were removed. It was expected that when the spans had been supported in this way, traffic could be suspended while the pier was being taken down to prevent its collapse, if the emergency should require; or, the spans having been protected against the collapse of the pier, traffic could be maintained until its collapse, and the remainder of the falsework could be put in in the meantime. The material for two double bents and for stiffening the overhanging ends of the trusses was assembled at the bridge and held there for several years, until after the reconstruction of Pier 4.

Further Studies.

Continuing into 1910, the entire matter was studied from every conceivable standpoint, including reconstruction of all the piers as single-track in their old location, reconstruction for double-track, an entirely new set of piers and shifting the spans, entirely new single- and double-track bridges, and rearrangement of the method of operation of the Little Rock Terminals so that the bridge could be abandoned, all traffic to use the main-line bridge. None of these plans was carried out, but the "watchful waiting" was continued.

A full report on this situation, with an expression of the attitude of the Engineering Department, was rendered on November 1st, 1910, by Mr. M. L. Byers, then Chief Engineer of Maintenance of Way, to Mr. A. W. Sullivan, then General Manager, extracts from the report being as follows:

"The conditions at this bridge are by no means satisfactory and are evidently such that it is entirely possible for them at the most inopportune time suddenly to become so serious as to prevent further use of the bridge until necessary action is taken to correct such new conditions. This may occur at a period of high water, which would prevent the use of the bridge for some six months to a year, although I do not believe there is serious danger of the loss of any of the superstructure of the bridge. It would probably be possible at any time (unless the failure were extremely sudden, which is unlikely) to drive such falsework as would be necessary to support the two spans resting on this pier, although in this case train service would have to be discontinued.

"There are a number of factors entering into the decision as to what should be done at this point. It may be that considerable time will be required to carry out the plans which may ultimately be de-

cided upon. It is impossible to determine how long the present conditions may continue. It may be that they will change almost at once, or it may be that they will not change for years. It would seem desirable, therefore, if possible, to decide upon a plan of action in case of sudden change for the worse so that no time will be lost in the preparation of plans or in necessary further study of the situation. To this end the following is submitted for your consideration:

"An entirely new set of piers for a single-track bridge, either in the present location or at one side of the present location, would cost approximately..... $250 000.

"An entirely new set of piers for double-track bridge, either in the present location or to one side of the present location, using the present spans, would cost approximately.. $450 000.

"A new double-track bridge (including the piers) would cost approximately..... $800 000.

"The present Baring Cross Bridge (at *Y*, see Fig. 2) will probably require renewal within five years at an estimated cost of approximately (for double-track)..... $900 000.

"In the event of the failure of Pier 4 alone, the probable cost of entirely rebuilding it for single-track would be about ..... $60 000.

"In the event of the failure of Pier 4 alone, the probable cost of entirely rebuilding it for double-track would be about ..... $80 000.

"With a view to determining if it would be possible further to defer final renewal of this pier through resorting to further temporary expedient, a very careful study of the situation has been entered into and a number of tentative schemes worked out, these varying in cost from $12 000 to $50 000; all of them, however, present so many possibilities of casualty, and the cost as compared with the decidedly uncertain benefit is so great, that none of them meet with my approval, nor do I know of any temporary expedient which I am willing to recommend.

"As before stated the further period during which the present temporary expedient can be continued is entirely uncertain and there is the possibility that it may fail on extremely short notice.

"Figure 8 is a general elevation of Pier 4 and the two spans resting thereon and shows in red the temporary falsework necessary to be put in place in order to prevent these spans falling into the river in case Pier 4 falls.

"Figure 9 shows the character of the temporary piers and the two plans indicate the amount and character of the work which must be done in order to save the spans in case of the falling of Pier 4. It must be borne in mind that it is quite possible this work, if it becomes

necessary, must be carried out at the time of extreme high water, and it is absolutely impossible to foretell the amount of time that will elapse between the time when the rapid movement of Pier 4 is detected and the time when the pier will actually fall—we may have time to place this falsework and we may not. The falsework has been ordered and will be kept on hand at Argenta.

"Figure 8 shows in yellow the additional supports that must be provided in case of the loss of Pier 4 before the bridge can be again opened to traffic. During the period of high water there will, of course, be more or less amount of danger that drift or boats would destroy this falsework—such is the risk involved in the present conditions.

"Quite recently Pier 3 has begun to move longitudinally at a much faster rate than heretofore, and it is, of course, possible that the conditions with which we are confronted at Pier 4 may at any time have to be met in connection with movement of the other piers.

"Recommendations.

"In view of the varying circumstances above enumerated, it is my recommendation that it be decided at once what policy is ultimately to be followed in connection with this bridge. I believe all of the facts essential to this determination are stated in this report and the matter would seem to be one of policy rather than engineering.

"Yours truly,

"M. L. BYERS,

"Chief Engineer, M. of Way."

PROPOSED MAT AROUND PIER 4.

For two or three years prior to 1911, the channel of the river had been moving away from Pier 4 and concentrating under the draw-span, resulting in the building up of the river bed around this pier with clear fine sand which early in 1911 covered the top of the crib and reached up on the masonry within 1 or 2 ft. of extreme low water. This sand evidently filtered into the crib and gave increased supporting power in addition to that provided by the sand that enclosed it. As a consequence, the movement of Pier 4 gradually slowed down, so that it was barely perceptible, and the great uneasiness that had prevailed for several years was partly allayed. The decrease in the movement was attributed to the steel bent placed at the back of the pier, by those responsible for that monstrosity.

In order to protect and preserve this sand surrounding the pier, the writer attempted in the fall of 1910 to secure authority to spend about $2 000 to construct a standard brush and pole mattress, about

150 ft. square, around Pier 4, to be securely bound together with wire and wire strand, and covered with rip-rap placed in pockets of the mattress to be formed by placing two sets of poles one across the other on top of the mattress to prevent the rip-rap from rolling off.

At the low stage of the river following the request for authority, the work could have been done without barges or other floating equipment and brought to completion in 30 days. The authority was not granted, and, after the next flood, it was not needed, as much of the sand had been washed away.

Rapid Movement of Pier 3.

While the river bed was building up around Pier 4, it was scouring away around Pier 3, the north rest pier of the draw-span, and this pier started to move quite rapidly directly up stream, at right angles to the axis of the bridge.

The movement in 1911 was more rapid and constant than any experienced previously in the other piers, and indicated the necessity for immediate action. The pier did not move dangerously in the direction of the bridge. Its natural tendency would have been to move south, as the plumb south face and eccentric bearings of the spans made the pressure heaviest on the south side. It was restrained from movement in that direction, however, by the rods and yokes which made this pier an anchor for the pull of Pier 4. In fact, during the frequent tightening of the yoke rods, Pier 3 was observed to move slightly north into a more erect position.

Plans for Reconstruction of Pier 3: Modjeski's Recommendation.

The first plan prepared for the reinforcement of Pier 3 was somewhat similar to the writer's last plan for Pier 4, which had been rejected. (See Fig. 20.)

It consisted of a reinforced concrete shell, tied to the old pier and resting on additional piles to be driven to rock around the old crib, as shown by Fig. 22. Here, however, there was no surrounding cofferdam, and it was deemed advisable to furnish protection for the piles and additional stability for the pier.

This was to be obtained by sinking around the pier mud-cell mattresses in layers about 4 ft. deep, with enough rip-rap in them to sink them. The result would be a building up of mattresses of

decreasing sizes and rock; sand sediment would immediately deposit until the top of the crib was nearly reached, when the entire mass would be covered by a heavy layer of rip-rap, the latter and the surrounding bed of the river would then be covered by another large protecting mattress. It was also the intention to bore holes in the crib and get in as much grout as possible. The writer believes this method of repair would have been entirely satisfactory; it also had the advantage of being very cheap. Five bids were received, the lowest (from an entirely reliable contractor) being about $8 500, which, together with the extras and incidentals, would probably have made the total cost of the work $10 000.

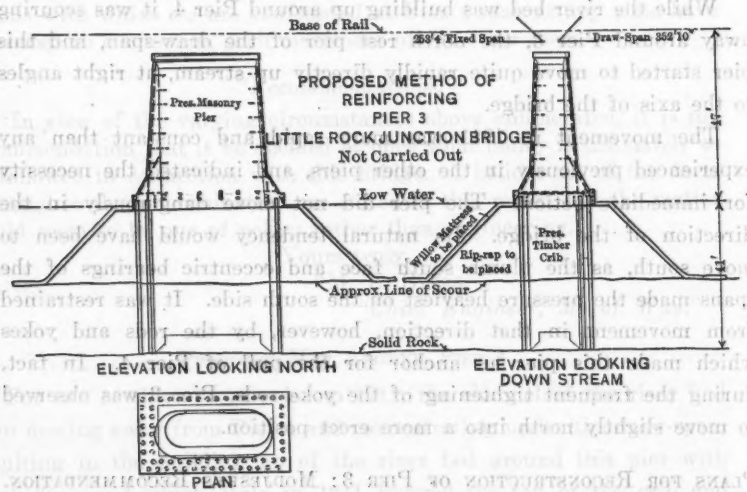

FIG. 22.

Before proceeding along these lines, however, the management desired an expression of opinion on the entire problem by a disinterested engineer, and Ralph Modjeski, M. Am. Soc. C. E., was consulted. The writer disclosed to Mr. Modjeski all the information in possession of the Railway Company on this subject, and accompanied him on an inspection of the bridge.

Copies of Mr. Modjeski's reports of August 5th, August 7th, and August 19th, 1911, are given in Appendix D.

It was arranged between Mr. Modjeski and the writer to bore holes down through the crib to rock, and this was done as far as

possible. It was found to be very difficult to get the pipe down; it would encounter solid timber, then sand, then loose rock, and combinations of all these. However, it was finally driven to the solid timber roof of the caisson, which was encountered at such an elevation as to leave no doubt that the cutting edge rested on rock, the level of the latter having been ascertained by running a jet pipe down through the sand around the pier. In sinking the pipe through the crib, efforts were made to secure the services of expert well drillers, but they all refused to guarantee to get the pipe down.

In brief, Mr. Modjeski recommended first that the sand in the crib of Pier 3 be removed and the crib filled with concrete. To accomplish that, he recommended driving 50-ft. triple-lap sheet-piling entirely around the pier, 6 ft. from the crib, and examining the old crib by partly removing the old planking. He also recommended that the up-stream end of Pier 3 be supported on shores resting on piles driven alongside the old cribs. This work involved supporting the spans on falsework.

A later report suggested placing the coffer-dam 12 in. from the old crib (if it was found that the filling of the cribs was sand which could be pumped out), excavating the material between the old crib and the coffer-dam, and sealing the bottom with concrete. Then the top crib timbers and the material inside were to be removed and the crib refilled with concrete, this work necessitating the support of the spans on falsework and taking down the old pier.

Later, he recommended rebuilding Piers 3 and 4 entirely by supporting the spans on falsework, putting coffer-dams around the piers, taking down the masonry, filling the cribs with concrete, and building new piers on them.

After considerable study of these latest recommendations, it was tentatively decided to follow Mr. Modjeski's first recommendation, but, on account of the great head against which pumping would have to be done (up to 50 ft.), steel sheet-piling was contemplated. Detailed estimates, however, indicated that this method would be quite expensive and uncertain, and would involve the hazard of carrying the spans on falsework. As a slight August rise in this river, a few days before, had swept away 1 000 lin. ft. of falsework at a bridge about to be erected farther up stream, those responsible for this bridge were not enthusiastic about carrying the spans on falsework.

Taking down the piers to rebuild them entirely would have been fully as hazardous, and very expensive.

Mr. Modjeski was then requested to pass opinion on the writer's plan of driving piling around Pier 3 and resting on it a reinforced concrete encasement around the pier, protecting the piling with mud-cell mattresses and rip-rap, as shown by Fig. 22. This he objected to as somewhat uncertain, as to results and the eventual stability of the pier.

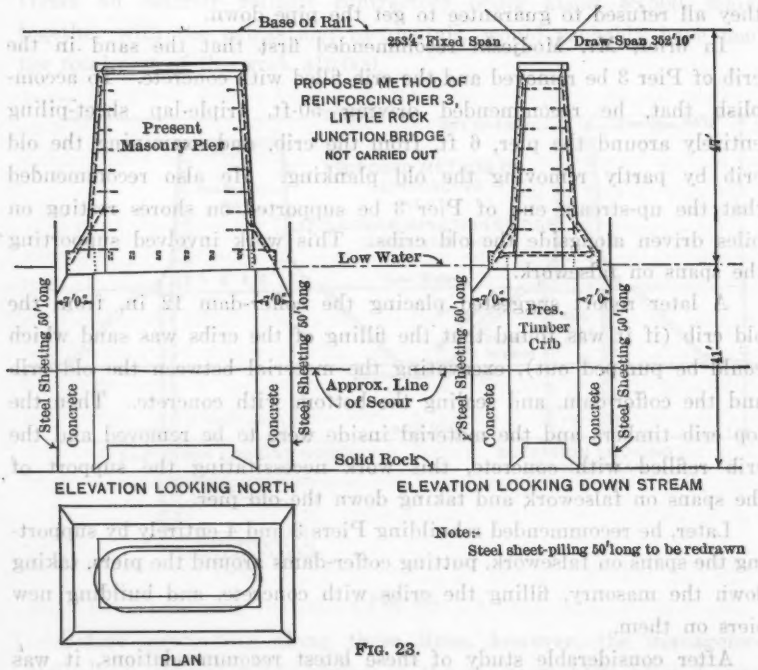

FIG. 23.

He was also asked to pass on a plan for driving steel sheet-piling about 6 ft. from the old crib, excavating the space between it and the old crib, and filling that space and the crib with concrete, the pier to be encased in a reinforced concrete shell, the whole to be done without falsework. Fig. 23 shows this scheme. He pronounced it to be very expensive, and said:

"To attempt to carry out this scheme without supporting the spans on falsework would seem to me extremely risky. The excavation around the crib would deprive it of considerable skin friction and would

probably open up more places through which sand now in the crib could leak out. The crib is now settling at the rate of 1 in. per month by the crushing of the timbers and this settlement may under the new conditions get so rapid as to endanger the whole structure.

"I am convinced that the pier could be built new for less money than the schemes shown on your plan. The new pier would probably contain about 500 cu. yd. of concrete and there may be another 500 or so necessary to fill the crib, making, say, 1 000 cu. yd. of concrete in all, besides, the work would be more certain of accomplishment and with the least amount of unforeseen expensive contingencies. I would therefore strongly recommend that this pier be rebuilt as stated in my former letter to Mr. Pearson. While it is very difficult to make even an approximate estimate on the cost of such work, my opinion would be that the new pier would cost very little more, if any, than the cheaper one of the two schemes in question, assuming in all cases that it would be desirable to support the adjacent spans, as there is great uncertainty how the present crib would behave while any work is being done around it.

"To rebuild the pier I would proceed as follows: Build temporary supports for the span, carrying the ends on a set of girders. Take down the old pier to the crib work. Drive wooden triple-lap sheet-piling or steel sheet-piling around the present crib. Excavate present crib and fill with concrete by methods which will become more apparent as the work goes along. Build the new concrete pier on top of the crib work thus reinforced."

The method of reinforcement that was finally brought to successful conclusion was first suggested by E. J. Pearson, M. Am. Soc. C. E., First Vice-President of the Railway Company. To overcome all uncertainties, he suggested securing the necessary additional supporting power by the use of a pneumatic caisson on each side of the old crib. This was extended, later, by adding caissons for the ends, forming an annular caisson surmounted by a coffer-dam, the space above the annular caisson to be filled with concrete, doing the same to the crib, and encasing the old pier in a new reinforced concrete shell, as shown by Fig. 24. This was also referred to Mr. Modjeski by the writer, in a letter setting forth the plan, as follows:

"I have never fully abandoned the idea which you first proposed of filling the pockets within the crib with concrete, and think if this work can be accomplished that the problem will be solved. I find upon investigation that it will cost very little more to sink an annular pneumatic caisson entirely around the crib than to carry out the scheme formerly proposed to use steel sheet-piling and concrete filling.

"I hand you herewith blue print, showing in red the construction of the caisson. I would construct the working chamber entirely of steel, as this can be done, by the use of second-hand bridge members now on hand at our store yard, for very little cost. I would leave off the inside wall of the coffer-dam above the roof of the working chamber, and construct a water-tight outer casing wall braced by latticed steel members extending up to low water.

"After sealing this working chamber with concrete, this outer shell would form a coffer-dam entirely around the pier.

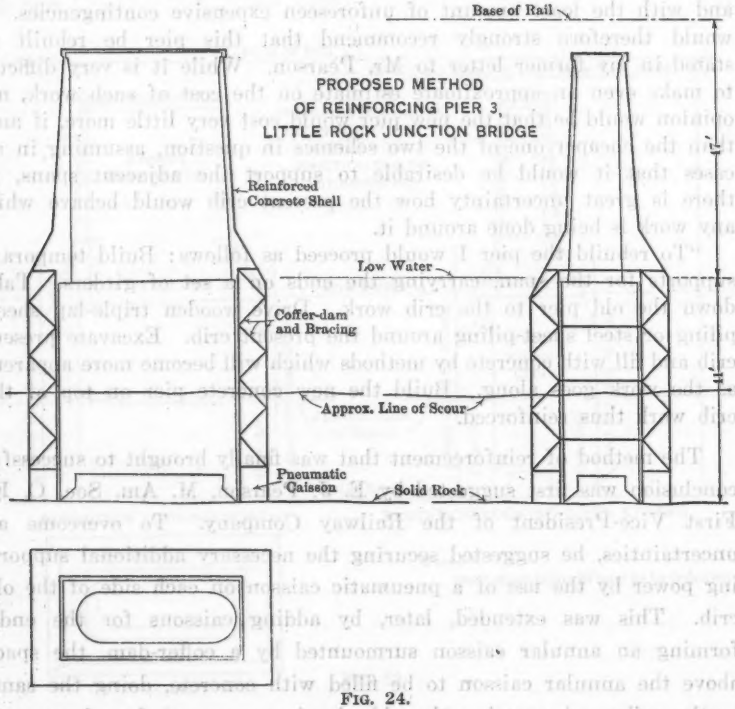

FIG. 24.

"The Arkansas River is subject to very rapid rise and excessive scour, and at such times carries an immense amount of drift. It is a hazardous proceeding at any time to carry spans on falsework in this river. During the construction of our Baring Cross Bridge, I understand, one of the spans was lost on this account. The Arkansas Bridge Company recently lost 1 000 lin. ft. of falsework in this same river a few miles above Little Rock.

"For this reason I do not like to place spans on falsework and take down the pier, except as a last resort.

DETAILS OF TIMBER COFFER-DAM FOR USE IN REPAIRS TO PIER 3, L.R. JC. BRIDGE

UNIV. OF MICH.

"If the pier starts to show signs of more rapid movement during the sinking of the caisson, traffic could be removed from the bridge temporarily and the sinking proceeded with. The pier could then be supported by temporary struts and shores resting on the steel members above the working chamber. After the caisson were sunk to the full depth and the working chamber sealed, I would pump out around the present crib and ram the pockets full of concrete, using a cement gun for the purpose, if necessary, and working from both sides of the crib. I would then complete the work by completely filling the space above the working chamber with concrete, and would then encase the present masonry pier with reinforced concrete above low water, both for the purpose of securing a symmetrical appearance and also to distribute a considerable portion of the load to the caisson."

Mr. Modjeski thought that this plan would be unduly expensive and, if carried out without falsework, entirely too hazardous. As he did not disapprove the scheme, however, it was adopted and carried out successfully.

Reinforcement of Pier 3 in 1912.

Unfortunately, the delay in arriving at a decision as to what would be done at Pier 3 consumed the best months of the year for the work. The change to pneumatic construction, necessitating the assembling and erection of the pressure plant and the construction of the caisson, further delayed the work up to the time of the flood period. The compressor plant was finally ready, and the steel caisson was shipped early in November.

Plate XXXIV shows the general outlines of the annular caisson and coffer-dam. The old records showed the old cassion under Pier 3 to be 14 by 31 ft., so the dimensions of the inner cutting edges of the new caisson were made 16 by 33 ft. The caisson was made of steel primarily to reduce its necessary width and consequently the displacement; the presence in the old bridge-material yard of a large number of duplicate second-hand floor-beams which could readily be converted into a caisson also encouraged the use of steel. The details of the steel caisson and the joint between its roof and the coffer-dam are shown on Plate XXXV. It was decided to build up a coffer-dam on the outer wall of the caisson, connecting the coffer-dam to steel lattice work or towers bolted to the roof of the caisson. These towers were provided in order to form the backbone of the rigid framework it was known

would be required to brace the new coffer-dam against the old crib during excavation.

The greatest care was taken in the design of the joint between the caisson and the coffer-dam. The timbers in the bottom row, 8 in. thick, were cut to fit the steel as closely as possible, and were set in a bed of hot tar and oakum. Surfaced timbers were used, and each layer was set on the next below in hot tar and caulked. Tar-paper was then placed over the timbers and 2-in. matched sheeting placed outside. The lower ends of the sheeting were driven into a groove, filled with hot tar and oakum, over the roof of the caisson, formed between the bottom timber and the upstanding leg of the angle at the top corner of the caisson. A space about ½ in. wide, between the sheeting and the angle, was then caulked. To bind all parts together effectually and to provide additional weight for sinking, a 2 ft. 6-in. layer of concrete was then placed over the roof of the caisson enclosing the bottoms of the towers. This concrete was banded to the steel roof by a large number of ¾-in. bolts, 21 in. long, fastened to the steel plate and extending vertically into the concrete.

The construction of the remainder of the coffer-dam was similar to that just described.

For the support of the annular caisson during the assembling and sinking, until the entire load rested on the river bed, the temporary support from the pier and trusses shown on Plate XXXVI was provided. Two 8 by 16 in. by 28-ft. timbers were placed across each end of the pier, as close as possible to the truss shoes. The coping stones at each end had to be removed in order to place the timbers low enough to permit the draw-span to swing over them. The ends of the timbers were held up by inclined struts gained into their under sides and set in grouted notches cut into the masonry of the pier. For additional stability and stiffness, the north end was connected by rods and struts to the end posts of the north span which, in turn, were stiffened by timber struts (similar to collision struts) running down to the first panel points. On account of the necessity of having the draw-span free to swing, it was not possible to provide corresponding connection with the end post on the south side of the pier.

Four 3-in. steel rods, threaded for their entire length, were passed through between the ends of the timbers, the nuts on them resting on heavy plates over the timbers, and the lower ends of the rods

reaching down to chairs made of rails supporting other smaller rods in pairs, on which the long sides of the caissons were supported near the water level after being floated out to the pier. The short sides or ends were then floated on barges and connected to the long sides by machine bolts. After the caisson was assembled and caulked, and all shaft, pipe, and wire connections were made, it was lowered into the water and the construction of the coffer-dam was started.

During and after the placing of the 30-in. layer of reinforced concrete over the roof of the caisson, the sinking progressed as fast as the work permitted. At the commencement of sinking, the river bed at the down-stream end of the caisson was several feet higher than at the up-stream end. As the caisson was lowered, the sand scoured deeper and deeper at the up-stream end and the workmen shoveled the sand from the down-stream end of the caisson into the water at the up-stream end until the cutting edge landed all around, following which the sand and other material, much of which consisted of heavy rip-rap and logs (almost petrified), was removed in buckets through the locks. The removal of the sand formerly against the down-stream end of the pier relieved it of pressure to such an extent that it partly righted itself. Trouble was continually experienced by the caisson catching on the protruding upper ends of the sheeting planks of the old crib, which had been torn loose by the settlement of the timbers and bulged by the pressure of the material escaping from the crib. These were particularly annoying before the cutting edge rested on the river bed, as the workmen had to pick their footing in the caisson. On all the old records available the caisson of the old pier was shown to be plumb, and a clearance of 2 ft. was supposed to have been allowed between it and the new caisson, but it was found that the old caisson had a sharp batter, which necessitated ripping off the old vertical sheeting before the new caisson could be landed. The cutting edge of the old pier was found on rock everywhere except at short dips which had been filled with concrete.

All the material within the new caisson had to be removed through the locks because sufficient pressure could not be maintained to force the sand through the blow pipes. This was caused by all the material between the old and new work running into the caisson and leaving the inner cutting edges usually exposed; and, when an attempt was made to increase the pressure to blow out the material,

the air would blow out under the inner cutting edge instead. As it was desired to avoid the resulting washing out of sand from the old crib caused by the commotion in the water during these blow-outs, the efforts to use the discharge pipes were abandoned. Mattson locks were used, and permitted the rapid removal of the material. No other particular difficulties were encountered.

The cutting edges were everywhere landed on rock, except over short dips, which were cleaned out and filled with concrete. The working chamber was filled with concrete carefully rammed to the roof, and before it had set, the lower sections of the shafting were also filled with grout.

Fig. 25 shows the steel caisson after it had been lowered partly into the water and construction of the coffer-dam had commenced. Fig. 26 shows the upper edge of the coffer-dam after the caisson had been landed and the reinforcing rods for the concrete encasement were being placed.

While the caisson was supported from the pier the inspector was required to compute daily and report weekly the weight supported. To guide him in the control of the work, and to avoid overloading the temporary supports, he was told the maximum weight that could be allowed, and was given a copy of a typical programme of work and a tabular summary of weights, together with the following instructions, the whole idea being to control the construction and sinking in such a manner as to keep the smallest load on the rods and take advantage of the immersion:

"Instructions.

"The support that has been provided for lowering the caisson into its final position is capable of safely supporting a total load of 325 000 lb. and the total weight of the caisson and coffer-dam and other materials above the caisson suspended from the rods should not exceed the above weight.

"There are five conditions that must be met in the sinking and founding of this caisson.

"They are as follows:

"1. Total weight of structure before lowering into water must not exceed the strength of the supporting rods.

"2. Total weight of structure decreased by the buoyant effect of the water displaced during sinking must not exceed the total supporting power of the rods.

PLAN SHOWING METHOD OF SUPPORTING AND LOWERING ANNULAR CAISSON USED IN REPAIRING PIER 3 LITTLE ROCK JCT. BRIDGE

UNIV. OF MICH.

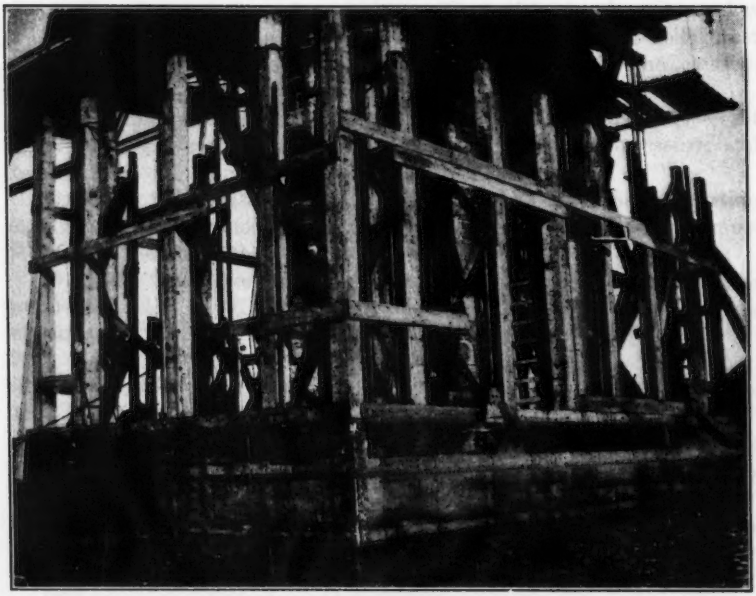

FIG. 25.—LOWERING COFFER-DAM AROUND PIER 3.

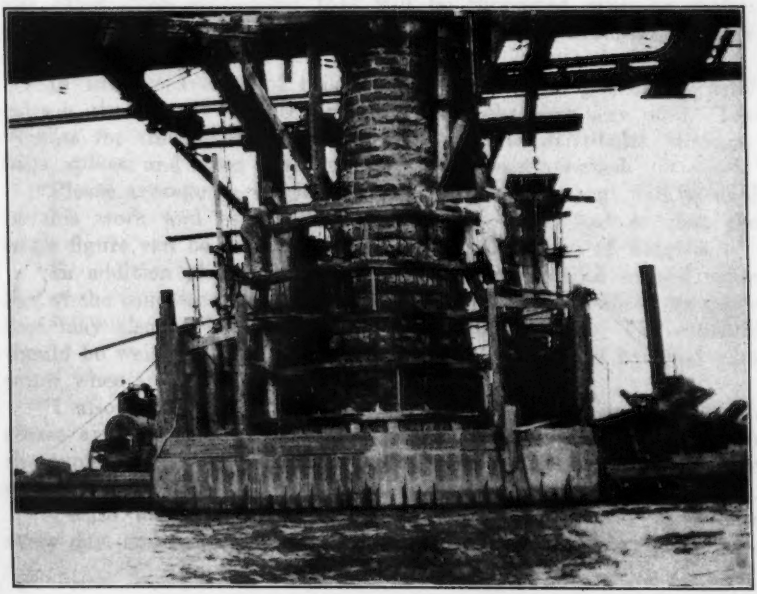

FIG. 26.—STEEL CAISSON AND COFFER-DAM AROUND PIER 3.

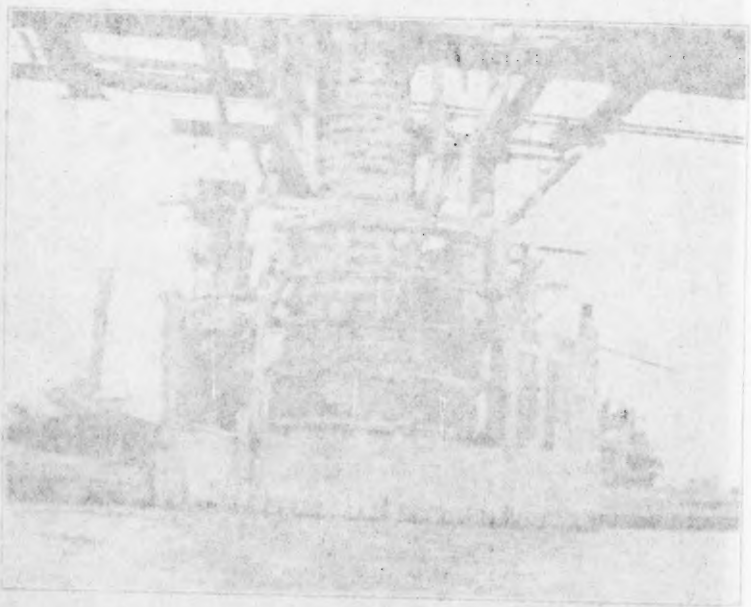

"3. In order that the caisson may be filled with air when it reaches the bed of the river, the total weight suspended from the rods must be approximately equal to the weight of water within the caisson, which will be expelled by the application of the air.

"It is expected that when the air is applied the unbalanced weight of the structure will be practically supported by the air pressure, and there will be only a nominal load on the rods.

"4. After the caisson lands on the sand, so that the supporting rods become slack when the nuts are turned, additional weight must be provided to force the caisson into the ground.

"5. After the caisson has reached bed-rock and the working chamber has been sealed by filling it completely full of concrete, there must be sufficient total weight to hold down the structure and prevent it from rising, on account of water pressure caused by the head of water from the surface of the rock to water surface, to be assumed acting over the entire base of the caisson.

"The attached table has been worked out in detail to show the various steps that should be taken in the construction of this caisson and coffer-dam.

"It is probable, of course, that you will not follow the exact procedure outlined, but you should follow it sufficiently close, so that the total weight given in column 'N' will never exceed 325 000 lb.

"Please note that the weights given in the table are assumed weights, and there has been omitted the weight of men, tools, lines, and other small equipment that will be supported upon or within the coffer-dam during sinking; the weight of such material must be added to the total weight.

"In the preparation of this table, the actual weight of the steel caisson, the towers, and the air shafts and locks have been used. The weights for timber, concrete, and iron, such as drift-bolts, through-bolts, spikes, and other small hardware have been assumed.

"Please arrange to weigh sufficient of the timber that will be used in this work and estimate its weight per cubic foot so that the latter figure can be used in your accurate calculation of weights.

"In addition please arrange to make up and weigh several cubic feet of the concrete that will be used, in order that its weight per cubic foot may also be known for use in the calculations. The concrete should be weighed when full of water as it will always be filled with water when submerged.

"I also hand you a number of white prints in blank, on which please arrange to enter notes and figures similar to those shown on the typical summary handed you herewith and arrange to send me one of these weekly with copy direct to Bridge Engineer, C. E. Smith.

"Please understand that this table must be posted up to date every day, and you must instruct your Inspector at the bridge to have

it always in shape for inspection and approval by the Bridge Engineer at all times, as the Bridge Engineer will inspect it at such times as he may visit the bridge.

"Please understand that an increase of the loads over the weights given you above would be very disastrous, as it would undoubtedly result in the breaking of some portion of the supporting structure, and might have a disastrous effect upon Pier 3.

"Please note by reference to the typical summary that the application of air to the caisson will make the structure practically self-supporting, but it is not safe to assume that the structure can be supported by the caisson full of air, as a leak in the caisson or in the supply pipe (which is very long), or a failure in the air compressor, or reservoir, or boilers, or a blow-out under the cutting edge, would immediately decrease the supporting power and increase the load in such a way as to throw a very heavy stress upon the rods, which might result in their failure.

"The caisson must be carefully adjusted level when it is first placed, and must at all times thereafter be kept perfectly level as the lowering of one corner faster than any of the others will result in racking the caisson and coffer-dam to such an extent that heavy leaks may be expected. It will be a very easy matter to keep this structure perfectly level by proper manipulation of the screws.

"In case one corner or one portion of the cutting edge rests upon an obstruction, the obstruction must be removed before further sinking is done. After the caisson reaches a bearing upon the bed of the river and the air has been applied, the structure will, to all intents and purposes, be floating, and it will be necessary to supply additional weight to force it down through the sand. This weight will be provided by placing concrete in the end compartments under water.

"The plans call for these compartments to be supplied with 2-in. forms for concrete for their entire height, so that, if necessary, the entire height of the structure can be built up at the ends to provide this additional weight. In addition it is desired that temporary 2-in. sheeting be placed on the inside of the long sides to prevent sand and other material running out of the old crib on top of the concrete. In no case, however, must any concrete be placed in the long sides, as it is desired that those spaces be left open until after the old crib is repaired.

"It will be impossible to add the weight in the end pockets while the structure is swinging from the rods, as it would not be practicable to provide a support of sufficient strength to support such a very heavy load.

"It is impossible to say how much concrete must be added in these end compartments to force the caisson through the material in

the bed of the river, as that resistance cannot be calculated, but the conditions must be conquered when encountered.

"After the caisson has reached bed-rock and the working chamber has been filled with concrete, the end pockets will be filled with concrete to a height of 25 ft. above the reinforced concrete roof, part of this material being placed during sinking through the sand and the remainder after the caisson has been sealed."

The weight of the steel caisson, the coffer-dam surmounting it, and the layer of concrete over the roof were not sufficient to sink the caisson after the river bed took the load off the rods. Inner forms for concrete in the ends of the coffer-dam were built up as the caisson was lowered, and concrete was deposited in them with bottom-dump buckets as the weight became necessary. Rods were placed in this concrete projecting from the inner face so as to form a bond with the remainder of the concrete to be placed later.

While waiting for the concrete in the working chamber to set, preparatory to pumping out the coffer-dam, a rapid rise came down the river and overtopped the dam on February 29th, 1912. The water subsided in about 6 weeks, and when pumps were started it was found that the coffer-dam had acted as a settling basin and was full nearly to the top with fine packed sand. The removal of this sand proved very burdensome, slow, and expensive, especially on account of the presence of the numerous braces. In the face of another rise, the dam was extended up to 52 ft. above the caisson, but the water went away over that again several times and stayed up for a considerable period, depositing more sand within the dam. The removal of this material, however, presented no difficulty other than the cost and delay. One pump easily controlled the leakage up to a 50-ft. head, giving a dry dam within which to work on the old pier. The filling of the old pier was found to consist of some rip-rap and more sand. In order to remove the sand, much rock had to be taken out. In fact, all the loose rock was removed with the sand, and only the tight rock was permitted to remain. The latter and the entire inside of the crib was washed out with a strong jet and then filled carefully with concrete. On account of the rather rapid settlement of the pier up stream, that end of the crib was first concreted, and, following the placing of that stiffener, the squeezing of the timbers at the down-stream end caused the pier to settle in the other direction, righting itself several inches. The entire space inside the coffer-dam

was filled with concrete, being brought up as the concreting of the crib progressed.

After filling the crib and the surrounding space with concrete, the pier was safe, but, as it was canted so much that it presented a poor appearance, and as the draw-span had only a very small bearing on the pier and was causing the upper courses of masonry to break away, the pier was encased in a reinforced concrete shell. As the new caisson had made the footing large enough, the reinforcement was built for double-track. Plate XXXVII shows the details of the reinforced pier.

The tie-bars at the bottom were placed through bolts cut in the pier, and grouted in. The bridge seats under the spans were entirely renewed in concrete finished at the proper level for double-track spans. The difference in level was made up by concrete pedestals placed in sections, as shown by Fig. 27.

No falsework was used for the support of either span, and the bridge was never out of service during the conduct of the work.

The outer surface of the timbers in the crib under Pier 3 were squeezed down at the ends an almost imperceptible amount. The upper timber was burst open on account of the crushing load.

Fig. 18 is a view of Pier 3 after the completion of the work. The equipment used in this work is listed in Appendix E.

Reconstruction of Pier 4 in 1912.

In anticipation of further work to be done at Pier 4, and in recognition of the fact that it was in much worse condition than Pier 3, it was decided to replace the rods and yokes holding Piers 3 and 4 to the intermediate span by a pair of cables attached in such a manner as to relieve the spans from the pull. As an anchor for each cable, two 4 by 1-in. eye-bars, together with substantial anchors, as shown by Fig. 28, were embedded in the new concrete of Pier 3 near the top just beyond the ends of the old pier.

Before proceeding with work at Pier 4, two 1¾-in. steel cables with cast-steel clevises were attached to the anchor-rods at Pier 3 and suspended from the span. At Pier 4 two 24-in. I-beams were laid on flat, north of the pier, and placed in contact with two 60-ton jacks which were placed horizontally with their bases securely braced against the face of the pier. Tension was put in the cables by the jacks, and the

old yokes were removed. It was found possible to kick Pier 4 over and it was actually righted about 6 in., but this was done more to get a good grip on it than in any effort to right it. The arrangement is shown by Fig. 29. It was such an improvement over the former yokes that no hesitation was felt about going ahead with the work.

On account of the success at Pier 3, all concerned were agreed that Pier 4 should receive like treatment, making use of the caisson and coffer-dam sunk in 1898. Soundings showed that the top of that coffer-dam had been butchered when the upper courses were removed, and it was necessary to smooth it by cutting off drift-bolts under water and removing loose timbers. It was decided to make an effort to extend the outer wall upward and make it sufficiently tight to permit the pump to expose the inner wall, and, after extending the latter, to rely on it for the rest of the work.

FIG. 28.

The contractor desired to use divers for this purpose, but on account of the great length of coffer-dam to be leveled off and extended upward (a total of 240 ft.), and the necessity for haste to make the most of the low-water season, the writer desired to avoid the delay which would be caused by the use of divers. The work was explained to the workmen, and a sufficient number were willing to do the work in the water for slightly increased pay. The depth of water was from 3 to 5 ft.; the time was summer and the workmen made extensive use of their natural "bare-skin" diving suits. The extension was made in a very short time, and a canvas having been stretched around the work, the dam was pumped out at the first trial. The inner wall was then very carefully dressed down in the dry and extended upward thoroughly water-tight, making it possible to pump out the water between that and the pier and start excavation. The concrete between the 1898 coffer-dam and the old crib was first removed on the south side, but was not disturbed on the north side until some time

later, after the yokes and cables were in place anchoring the pier to Pier 3.

The removal of the material down to rock was slow and tedious. The old coffer-dam had been badly racked during sinking, and large leaks were found all the way down. They were overcome, and the rock was laid bare and covered with concrete up to the top of the caisson of the old pier, after which the crib was cleaned out, filled with concrete, and surrounded as at Pier 3.

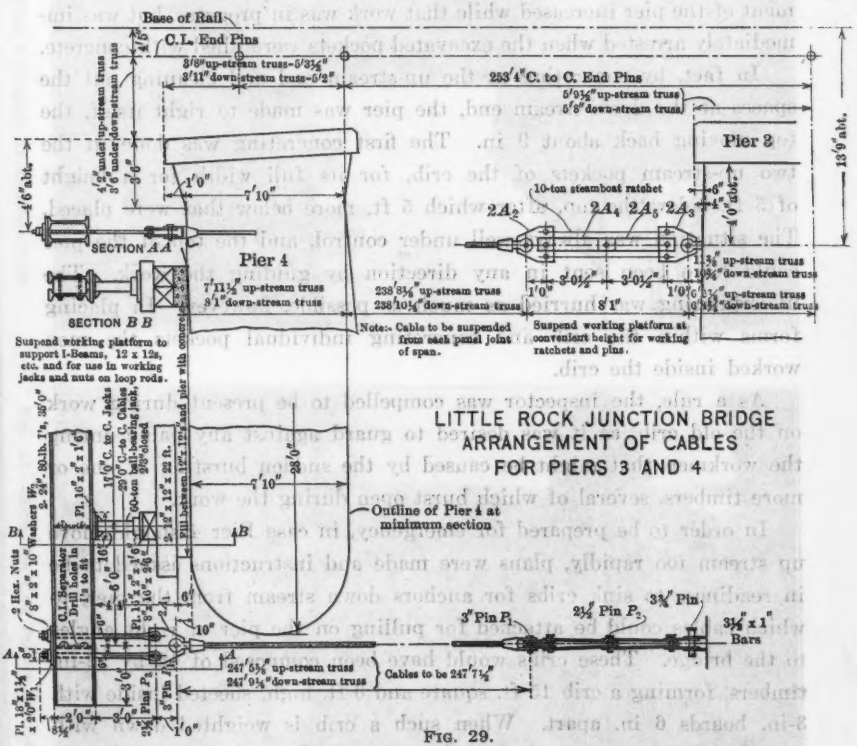

FIG. 29.

There was always a great flow of water from the south side, and in excavating down it was found that it came through under the cutting edges of the 1898 coffer-dam where a dip in the rock had been bridged over and was supposed to have been filled with concrete, but apparently was not. Several bad blows, carrying many yards of sand and flooding the excavation, occurred under the 1898 caisson, and it

was not possible to pump down to the bottom until after the material had been removed and the leak stopped by placing a sealing course of concrete under water.

Some of the timbers were crushed to 6 in. in height, and on account of the inclination of the pier new cracks developed in the timbers while the excavation progressed. The weakest portions of this crib were concreted as they were reached. Attention was given to the up-stream end, and excavation was first made there. The movement of the pier increased while that work was in progress, but was immediately arrested when the excavated pockets were filled with concrete.

In fact, by concreting at the up-stream end and cleaning out the spaces at the down-stream end, the pier was made to right itself, the top moving back about 9 in. The first concreting was done in the two up-stream pockets of the crib, for its full width for a height of 5 ft. below the top, after which 5 ft. more below that were placed. The situation was always well under control, and the top of the pier could have been sent in any direction by guiding the work. The underpinning was hurried as much as possible, however. In placing forms within the crib and concreting individual pockets the men worked inside the crib.

As a rule, the inspector was compelled to be present during work on the old crib, as it was desired to guard against any panic among the workmen that might be caused by the sudden bursting of one or more timbers, several of which burst open during the work.

In order to be prepared for emergency, in case Pier 4 should move up stream too rapidly, plans were made and instructions issued to be in readiness to sink cribs for anchors down stream from the pier, to which cables could be attached for pulling on the pier at right angles to the bridge. These cribs would have been composed of 12 by 12-in. timbers, forming a crib 15 ft. square and 6 ft. high, sheeted inside with 3-in. boards 6 in. apart. When such a crib is weighted down with rock and dropped on the bed of the Arkansas River it becomes buried immediately and forms an almost immovable anchor. It was not found necessary to sink such cribs, however.

No falsework was used while Pier 4 was under reconstruction; the pier carried traffic at all times.

Figs. 30 and 31 are two views of Pier 4 during the reconstruction. The old timber yoke and rods connecting to the trusses, placed in

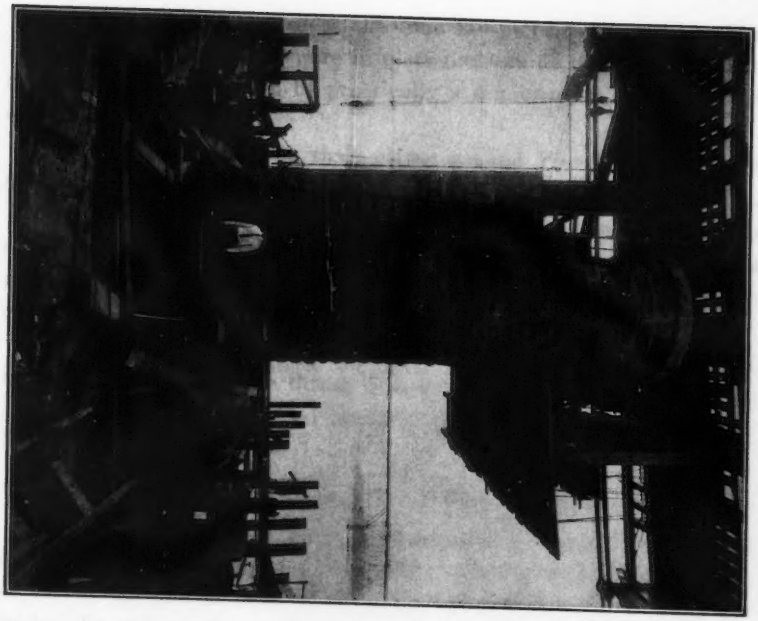

FIG. 30.—END VIEW OF PIER 4 DURING RECONSTRUCTION.

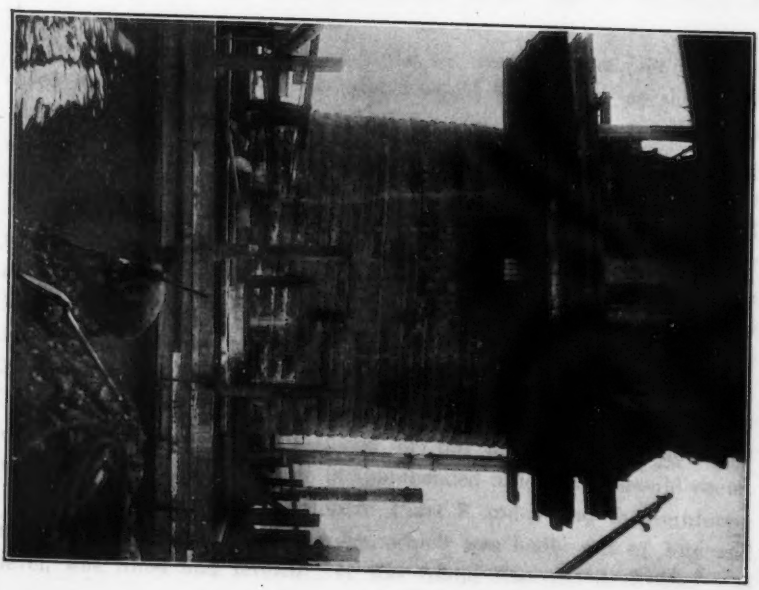

FIG. 31.—SIDE VIEW OF PIER 4 DURING RECONSTRUCTION.

1908, had not been removed at the time the picture was taken. The I-beams and 1¾-in. cables were in place and can be readily seen. The completed pier appears to be practically a duplicate of Pier 3, shown on Fig. 18.

The reinforced concrete shell placed around Pier 4 is practically a duplicate of that placed at Pier 3. It is shown on Plate XXXVIII. The tie-bars at the bottom were passed through the pockets in the crib and concreted in, instead of being passed through the pier. At this pier the ends of the spans were shifted sideways to permit the construction of each concrete pedestal in one piece.

As Pier 5 had moved north somewhat in the past, as a result of its own weakness and the thrust from Pier 4, anchors were buried in Pier 4 and the cables shifted ahead, Pier 4 now acting as an anchor for Pier 5.

Reinforcement of Top of Pier 5 in 1913.

The small tops of these piers, their reported movement, and the frequent shifting of the spans, all contributed to a very poor condition of the bridge seat on Pier 5, on which the stones were breaking out under the end of the south span which rested close to the edge of the pier.

To strengthen the bridge seat, the top 10 ft. of the pier was encased in a reinforced concrete jacket about 9-in. thick, as shown by Fig. 32. The sides were connected by passing the reinforcing rods around the curved ends of the pier and also by three sets of rails set vertically in the reinforced concrete at the middle and quarter points of the length of the pier. The lower ends of these rails were attached to the pier by 2-in. anchor-bolts set in grouted holes. Their upper ends were connected by 2-in. rods extending across the pier tops in channels cut in the bridge seat and filled with concrete. All cracks in the pier top were carefully grouted. The bridge seat appears to have taken on a new lease of life.

It is expected that, as Pier 5 is quite a distance from the ordinary channel, there is little likelihood of the material surrounding it washing away, and no trouble is apprehended unless that should occur.

Following the reconstruction of Piers 3 and 4 and the reinforcement of Pier 5, the entire bridge, which was badly out of line and level, was lined and leveled. It was found that the draw-span was

somewhat twisted and one end hung lower than the other. As far as could be done without injury to the span, the inequalities were corrected.

The work on the three piers and spans cost about $100 000, which is much more than it would have cost had the work on Pier 3 been started earlier and the floods avoided.

The reinforcement of Piers 3 and 4 was executed on a force-account basis by Bates and Rogers Construction Company. The adjustment of the spans and the reinforcement of Pier 5 were executed by the Railway Company forces.

Instrumental Observations.

Various systems of observations had been used to get a record of the extent and character of movement, but they had not been closely followed up, so that the old records of movement are intermittent. No figures are available previous to 1905, and measurements prior to 1908 were not strictly comparative because the errors of observation were often greater than the movement, but over any extended period they indicated the general trend of the movement. In March, 1908, triangulation monuments were placed on Pier 4 and on the river banks for monthly observations. The movement of the piers and spans, however, was such that it was necessary to change the points continually in order to get a clear view through the bridge, and as that rendered the observations of questionable value, this method was abandoned in 1910 for that in use at the present time. The character of the observations taken since that time is best described by the following copy of the instructions issued to observers on July 15th, 1910:

"Instructions for Taking Observations on Piers of Little Rock Junction Bridge, Little Rock, Arkansas.

"St. Louis, Mo., July 15th, 1910.

"Character of Observations.

"The observations consist of four independent determinations, as follows:

"*Line.*—Determining the location of two points on each pier by line relative to fixed monuments on shore.

"*Distance.*—Determining the location of said points by measurements from fixed monuments on shore.

"*Grade.*—Determining the elevation of said points with reference to established bench-marks.

"*Soundings.*—Determining profile of river bed entirely across the river at the center line of track and at the up-stream and down-stream ends of the piers.

"General Remarks.

"The observer must provide himself with a complete copy of these instructions and accompanying drawings, and study them carefully before making the observations.

"The two points on each of the piers consist of copper plugs, ¾ in. in diameter, set in the masonry, located and placed as shown on Sheets 1 and 4. The fixed monuments on shore consist of short sections of old rails set in the ground, located and placed as shown on Sheets 1, 2, 3, and 4.

"The points on the piers and the monuments on the Argenta side of the river being several feet below the level of the track, it is necessary to use a plumb-bob over each point. In order to protect the plumb-bob and string from atmospheric disturbances, a box, open at both ends and cut to proper length, as shown on Sheets 4 and 5, has been provided for each point. The boxes for Monuments *I* and *K* are fixed in position at the top end by hinges screwed to the under side of the bridge. This enables the boxes to be swung aside when desirable.

"The boxes for the points on the piers are marked *x*, *y*, etc., to correspond with the point over which they should be used.

"The boxes are held in place by cleats connecting their tops to the ends of the bridge ties. Those on the west or up-stream end of the piers extend 6 in. above the top of the floor-beams, those on the east or down-stream ends of the piers extend up to the under side of the plank walk. The boxes are provided with adjustable cross-arms for supporting the plumb line. The cross-arms for the west boxes may be tacked directly to their top; those for the east boxes may be tacked to blocking supported on the plank walk.

"Points are located on these adjustable cross-arms directly over the points on the piers by means of a plumb-bob suspended through the box directly over the respective points on the piers.

"Monuments *B*, *C*, *I*, and *K* are to be used for establishing the reference lines.

"The direction and character of the wind, the nature of the weather, distance base of rail to water surface, temperature, and any other conditions affecting the observations must be recorded on each occasion.

"Method of Procedure for Line.

"Set the transit over Monument *C* and check line *A B C D*; then set it over *H* and check lines *G H I* and *H J K L*; set over *M*

and check lines $M\ J\ I$ and $N\ M\ K$. If these lines check, the monuments may be assumed to be correct. With transit at M and foresight on I the location of x_7 may be checked.

"Next move transit up to deck of bridge and set it over point K, sighting on C and establishing line at points, y_7, y_6, y_5, and y_4; then over point I, sighting on B and establishing points, x_6, x_5, x_4, and x_3.

"Next move transit to other end of bridge and set it over C, sighting on K and establishing points, y_1, y_2, y_3, and y_4.

"The distances between the points thus established and the original points formerly established on the copper plugs measured on the cross-arms, at right angles to the line of sight, must be recorded, as these distances indicate the movement of the piers in an east and west direction, at right angles to the direction of the bridge.

"This observation must be taken at least twice, the observers changing places and repeating all operations until their observations check.

"Method of Procedure for Distances.

"The measurements from fixed point on shore are made along lines $B\ I$ and $C\ X$, points B and C being taken at Station 0, and the station of each of the points, x, y, etc., as well as I and K being recorded.

"On line $C\ K$ the tape is permitted to rest on the tops of the floor-beams; on line $B\ I$ (which follows the footwalk) wood blocks about 4 in. high must be placed over each floor-beam to reproduce the conditions of support obtained on line $C\ K$ and to eliminate the effect of the temperature of the walk on the tape.

"The distances are measured with a 200-ft. tape stretched to a tension indicated as 15 lb. on a spring balance. Monuments S_1 and S_2 have been carefully set 200 ft. apart for standardizing the tape, which is correct at 62° Fahr. For other temperatures the measured distances must be increased (+) or decreased (—) by the amounts shown in the following table.

"Average Temperature.

"Method of Procedure for Grades.

"The top of the steel rail in Monument *C* is the bench-mark elevation. For purposes of checking, any other monument may be used, the elevations being shown on Sheets 2 and 3.

"Set the level about half way between *C* and the south abutment, use point *y* for turning point. Move level to middle of first span and use point *y* for turning point. Continue across all the spans and back in this manner, checking on bench-mark *C* and taking readings on all points on piers in each direction for a check.

"In case the levels check upon returning to *C* and the two readings on each point check, this observation need not be repeated. Otherwise it must be repeated until a check is obtained.

"Method of Procedure for Soundings.

"Soundings shall be taken along the lines $P\ P_1$; $P_2\ P_3$, and $P_4\ P_5$, shown on Sheet 6, preferably by use of a lead line from a boat, except where the ground line is above water, where it can be taken by a weighted tape from the bridge floor. The distance from base of rail to water surface shall always be recorded.

"Soundings shall be taken close to the foundation under each pier, but far enough out to miss it, and at every second floor-beam of each span (about 50 ft. apart).

"This observation for soundings need be taken only once, there being no necessity for its repetition."

Fig. 33 shows the location of the base lines, points on pier, transit points, and other monuments. No movement has been detected in the pivot pier since the repairs in 1898; no movement has ever been detected in Piers 1, 6, and 7.

Fig. 34 shows the movement curve for Pier 3; practically no movement was detected up to 1908. In that year, following the application of the rods and yokes to the ends of the span resting on Piers 3 and 4, Pier 3 moved north (parallel to the bridge) about 10 in. from 1908 to 1913, during which period the reconstruction was carried out, since which work the pier has been stationary. No movement east or west (at right angles to the bridge) was detected in Pier 3 until the summer of 1910, when, for no apparent reason other than the deep scour of the river around the pier, it started up stream at the rather rapid rate of 9 in. in 14 months, the up-stream end settling several inches. This movement brought about the reconstruction of the pier in 1911 and 1912, during which it was found possible, by controlling the underpinning, to make the pier partly right itself, the curve showing that the top moved back (east) about 6 in. during the work.

FIG. 33.

Fig. 35 shows the movement curve for Pier 4. The position of the pier in 1898 made it evident that the movement had taken place for a long time, but no record exists prior to December, 1905, at which time the pier was more than 2 ft. out of place in the direction of the bridge and more than 1 ft. out of place at right angles to it. The curve shows that the movement continued and increased about 12 in. parallel to the bridge and several inches at right angles to it up to September, 1912, when the reconstruction was so well under way that the movement was well within control, as indicated by

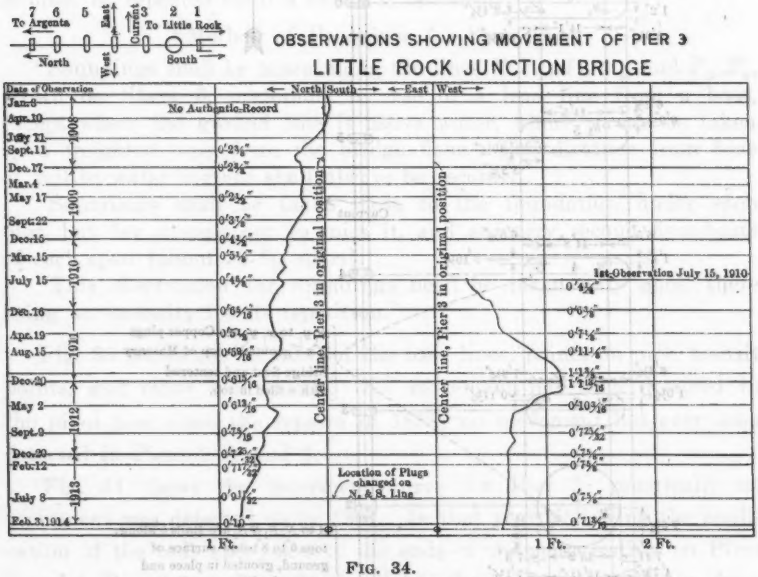

FIG. 34.

the fact that the pier moved back parallel to the bridge about 6 in. and at right angles about 9 in. after having greatly increased its regular movement by going over 12 in. in a little more than 2 months while the excavations around and within the crib were in progress. Since the reconstruction this pier has been stationary.

Fig. 36 shows the movement curve for Pier 5. No movement has ever been detected at right angles to the bridge, but there has been intermittent movement parallel with it. No movement has been detected since the application of the cables anchoring this pier to Pier 5, and no further movement is expected.

FIG. 36.

Prior to the reconstruction of Piers 3 and 4 the observations were taken every 30 days, as a rule. During the reconstruction the piers were sometimes under continual observation. Since that time and for the future it is the intention to take observations every 6 months, unless further trouble develops.

The alignment on this bridge was bad during the movement of the piers.

Fig. 37 shows several soundings under the bridge and indicates the extent to which the depth of river bed varies.

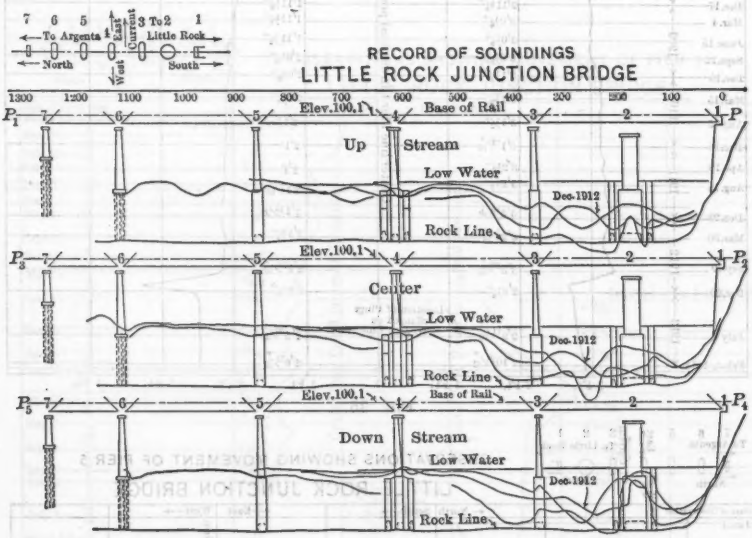

FIG. 37.

The observations, investigations, maintenance, and reconstruction of this bridge, since December, 1907, have been under the supervision of the writer. In the detailed designs and supervision of the last reconstruction, he was assisted by S. L. Wonson, Assoc. M. Am. Soc. C. E., the present Bridge Engineer of the Railway Company, and in the execution of the work on the ground all credit is due to Mr. F. L. Marshall, Assistant Engineer. Their courage, energy, persistence, and ingenuity made a successful accomplishment out of what might have been a deplorable failure.

APPENDIX A

REPORT OF W. M. PATTON.

"BLACKSBURG, VA., April 9th, 1898.

"MR. E. FISHER,
"Engineer, B. & B., Mo. Pac. Ry.,
"Pacific, Mo.

"DEAR SIR: The examination of the condition of the foundations of the piers of the Little Rock Jct. Bridge were made for the following purposes:

"1st. To determine the character of the material surrounding the caisson and crib of the piers.

"2d. The condition of the timbers in the crib and the character and condition of the filling in the pockets of the crib.

"3d. The depth of the water and of the earthy material between low water and rock.

"The first two have been determined to my entire satisfaction. The third has not been determined completely and fully, this, however, is only necessary in order to give definiteness to the maximum depths to which the caissons will have to be sunk, as the basis of an unconditional bid by Contractors, and in no wise affects the proper design of the structure required in order to prevent further settlement and to enable us to level the present piers. These depths have, however, been determined to such an extent that I feel safe in saying that the maximum will not exceed 40 ft. from low water surface.

"The detailed report of the examinations made will be found on separate sheets enclosed in this.

"After a careful study of the conditions, based upon information obtained, the examinations of other engineers, and finally and more satisfactorily from my own examinations, I am fully satisfied that the cause of the trouble arises from resting one side of the caissons on rock and supporting the opposite side upon some inferior material and this defective construction, rendered more so by the necessity of placing the masonry of the structure nearer one edge of the crib, owing to locating or sinking the caissons out of line, and resulting in a greater intensity of pressure on some portions of the foundation bed than upon other portions.

"The examinations indicate that the masonry is only a few inches (in fact practically on one side of the crib) from one side of the crib, whereas it is only 2 ft. 8 in. from the edge of the opposite side, consequently the axis of the pier is fully 1 ft. 4 in. nearer the west and north sides of the caissons than the east and south sides. The bottom area of the caisson is 1 024 sq. ft.; the estimated load (pivot pier) is 4 496 500 lb., equivalent to a load of 4 400 lb. per sq. ft. This is

nearly, if not quite, the maximum allowable unit pressure. The eccentricity of the load gives as the maximum pressure over 4 300 lb. pressure per sq. ft., which is in excess of the allowable load upon anything but solid rock. This condition is more noticeable at Pier 4 than at Pivot Pier. At Pier 4 the uniform pressure per square foot of foundation bed is 6 200 lb., and owing to the eccentric loading the maximum pressure per square foot must be over 7 000 lb., a unit load far beyond anything permissible.

"These conditions fully account for the settling of the piers, here it may be asked, why has the settlement been toward the west and not toward the north, if at both of these points the rock is at a greater depth than at the south and east corners? It may be answered that:

"1st. The filling between the bottom of the caisson and the rock at the north corner may be better than at the west corner.

"2d. The west corner, being the up-stream corner, is scoured out to a greater depth than the north corner, thereby reducing to that extent the supporting power of the material.

"The depth of water at the east corner was found to be 16 ft. 9 in., at west corner 22 ft. 5 in. and this, notwithstanding the large amount of rip-rap deposited at and on either side of west corner, and, moreover, other conditions might exist as to why this settlement to the west occurred, rather than toward the north, even assuming that the elevation of the rock at the west corner is the same or even higher than the north corner. We are, however, dealing with fact not a theory, and whatever may be the difference of opinion as to the cause of the trouble, the important question is, what is the proper and best remedy, under known, not probable conditions. Clearly any design with this object in view should enable us to solidify the present material under the westerly half of the caisson, or remove that material and substitute some more solid material for it:

"1. To solidify the material at present between the bottom of the caisson and the rock. The only practicable and available method is known as the Harris' process, which consists in injecting pure (liquid) cement under pressure into the material, thereby converting it into concrete in place. This method while perhaps never employed in a case exactly similar to the one under consideration, has proved to be effective under other conditions and where the original material is clean sand, I am satisfied it is a safe and effective method. The examination showed a remarkably clean sand and gravel from the bed of the river to rock; at the east corner a thin layer of clay and silt, at about 7 ft. above the rock; but as it would only be necessary to apply, at any rate for the present, the process to that half of the caisson from the south through the west to the north, the presence of this clay at the east corner would be of no consequence, and its

distance from the rock would render it not worthy of consideration at all. The conditions are, therefore, exceedingly favorable for the application of the Harris' process. It will be a, comparatively speaking, rather inexpensive process, even recognizing it as patented, probably $10 000 would cover the entire cost. I do not, however, recommend this method, owing to the uncertainty that would necessarily exist as to the results obtained, which could only be determined by time, and in addition it would preclude the possibility of raising the pier to its proper vertical position. If you see proper you can correspond upon the subject with the Harris Company of New York.

"2. To remove the present material under the caisson and substitute it with concrete; the available methods to accomplish this are:

"1st. The Poetsch-Sooysmith freezing process.

"2d. The ordinary coffer-dam.

"3d. The pneumatic caisson, using the old caisson and crib for one of its walls.

"4th. An independent caisson and coffer-dam constructed entirely or partly around the old caisson and crib.

"1st. An ordinary coffer-dam let a few feet into the bed of the river and freezing a wall of the material below to the rock. This method can be relied upon as effective, and the only consideration is in respect to the cost. You can correspond with Wm. Sooy-Smith of Chicago or Charles Sooysmith of New York.

"2d. The ordinary coffer-dam is probably hardly worth considering, as it would be extremely difficult to make a water-tight dam in the kind of material around these piers and of the depth required. There would be many risks to incur of failure and the saving in cost, if any, would hardly justify the employment of such an uncertain method.

"3d. The method that at first seemed to me the best, surest, and most economical was to use a pneumatic caisson, making the old crib and caisson one of its walls. My own examination of the crib and its filling, which entirely corresponds with the report of the divers, discloses the fact that the crib is filled with small rip-rap, sand, and gravel, the latter in all probability was washed in subsequently to the completion of the structure, through the open sides and pockets. This condition convinced me that at least it would be a very risky method, and the risk is so great that I do not consider it justified by the saving in cost, if it should prove successful.

"4th. I have, therefore, been compelled to recommend the adoption of an entirely independent caisson, entirely or partly surrounding the old crib and caisson, leaving a working space of 6 ft. between the old and new caisson. The working designs for this structure with bill of material, estimate of cost and full detail, are sent by express to your address.

"While this design in many of its main features is similar to that designed for many piers constructed by me, there are some novel features introduced which are justified and demanded by the novel conditions, to which it is adapted. The design commends itself for the following reasons:

"1st. It gives absolute assurance of success, in exposing the material between the bottom of the caisson and the rock, and affording the opportunity of removing that material and substituting in its place concrete, which will unquestionably prevent further settling, due to the yielding material at present under the caisson.

"2d. It affords the opportunity of raising and leveling the pier in its original and proper position.

"3d. It affords the opportunity of making a thorough examination of the timbers of the crib and the caisson, and of repairing any damage done to the crib, arising from the settling.

"The report of the diver, confirmed by my own examinations, leads me to believe that some damage has been done to the upper timbers and the sheathing planks during the settlement, and I consider it important to either restore the sheathing plank or to fill the pockets to a certain distance inward on the several faces to hold the filling in the crib. This being done, the present filling, although of small stone, sand and gravel, will no doubt be sufficient and satisfactory.

"During the examinations recently made, a number of 12 by 12-in. timbers were bored entirely through at depths varying from 10 to 30 ft. below the water surface, and in every instance the timber was found to be firm and sound.

"The design shows the new caisson as constructed entirely around the old one. It may not be necessary to construct it around more than one-half of the old one; that is, around the west corner and extending the length of the side toward the north and south corners, respectively. This, however, forces us to utilize the old caisson as one wall of the coffer-dam, and it is possible, if not probable, that this will not hold the water back, so that the space between the two caissons may be pumped out. However, this half can be sunk as a section and the other half sunk, if found necessary; no change in the design will be necessary. It will be necessary to make a water-tight connection between the ends of the new caisson and the old caisson at the north and south corners. It will also be necessary to bolt two channel irons at each end of the new caisson, so that, in the event of adding the second section around the east corner and extending the south and north corners, the two sections can be united so as to form a water-tight joint.

"The estimated cost of the caisson and coffer-dam constructed entirely around the old caisson is about $40 000, and of the half caisson and dam about $20 000 to $25 000.

"The filling above the deck of the caisson required to sink the caisson may be of any material desirable, as far as practicable, the material taken out of the working chamber during the sinking may be used for this purpose, and in fact this should be required, or at any rate no payment should be made for the filling if the contractor prefers to get it from other sources; also the material between the new caisson and the old one can be dredged during the process of sinking and used for filling. This, however, should be done with judgment, as it will evidently be unwise to remove the material at and near the west corner of the old crib until we have at least given some temporary support to the caisson to the west of the center line of the pier, or that diagonal line joining the north and south corners.

"Owing to the relatively small depth of the earthy material, through which the sinking is to be done, it is possible that no filling above the deck of the caisson will be necessary. Filling this space with water may answer every purpose. It may not be necessary to fill the working chamber itself if a water-tight joint can otherwise be formed between the bottom of the caisson and the rock. If not, a concrete or clay puddle must be used of sufficient thickness to secure water-tightness. Owing to the shaly and inclined nature of the rock, it may be necessary to cut a longitudinal trench in working chamber and to fill this with puddle or concrete in order to cut off seeping water along the seams of the rock. These are matters to be determined by observation and the exercise of good judgment at the time. It is proposed to obtain water-tightness of the structure above the deck of the caisson by means of caulking the timbers and plank walls, and not by means of the filling material. One or both walls should be caulked for this purpose.

"The air-tightness of the working chamber must be secured by thorough and perfect caulking. These and other similar matters will be embodied in the outline of the specifications accompanying the drawing. You will note the upper half of the structure is so designed and connected that it can readily be removed. The lower half being below the bed of the river, or at least of sufficient depth below the water surface not to interfere with navigation, can be left in place. I, therefore, respectfully submit the accompanying drawings, marked Sheets 1, 2, and 3, accompanied with the following suggestions and recommendations.

"1st. Sinking the caisson in two sections, the one section extending from the south corner around through the west to the north corner, which may be all that will be required, and sinking the second section from the south corner around through the east to the north corner, if found necessary, owing to the open condition of the old crib.

"2d. Excavating the material from the north and south corners of the old crib and between the old and new structures to a point, say,

half way between the south and north, respectively, and the west corner, removing the loose material from beneath the old structure and replacing with concrete, or some temporary support.

"3d. Then excavating the material from, at and near the west corner, exposing the space below the old structure, removing the loose material and replacing the concrete or some temporary support. This temporary support contemplates raising the pier to its original and vertical position.

"4th. If practicable, I would suggest supporting the superstructure on temporary supports during the time occupied in cleaning out the material between the old and new structures and until the permanent filling is in place and has had a reasonable time for hardening.

"5th. For the purpose of lifting the pier, I would recommend the employment of hydraulic jacks. It is estimated that hydraulic jacks having a main cylinder of 3.5 in. diameter and a pump plunger of ¾ in. diameter, will raise 20 tons of 2 240 lb., without excessive steam pressure. Upon this basis there will be required from 30 to 35 jacks, assuming that the superstructure is temporarily lifted from the pier; the cost of this portion of the work will be little more than the cost of the jacks.

"6th. With the structure supported on jacks the removal of the loose material and substitution of concrete (for which the best Portland cement should be used) can be proceeded with without risk or danger; otherwise this work should be carried on in sections, and precautions taken not to reduce the supporting resistance, as it now exists, at and near the west corner, until the caisson is well supported, two-thirds to three-fourths of its area. The amount of concrete estimated for filling under the caisson will not exceed from 150 to 200 cu. yd.

"7th. As the design submitted will afford ample opportunity for a full examination of the caisson and crib, I would suggest filling the open spaces on the sides with concrete to the depth of from 12 to 18 in., forming a wall to hold in place the present loose and imperfect filling. A good sheeting of timber, well bolted to the timbers of the crib, will probably answer every purpose.

"The character and extent of this work necessary, can only be determined at the time.

"With the drawings you will find a bill of material, estimate of concrete required, and a detail report of the character and extent of the examinations and the information obtained.

"Trusting that you will find everything in satisfactory shape, I am,

"Yours truly,

"W. M. PATTON.

"P. O. Box 209
"BLACKSBURG, VA.

"In the event that it is deemed better or found necessary to entirely enclose the old structure with caisson and coffer-dam, it may be found more economical and satisfactory to excavate the rock at and near the south and east corners, and to lower this portion of the structure, thereby bringing the pier to its original vertical position, rather than lifting the westerly portion by means of hydraulic jacks."

REPORT IN DETAIL OF THE EXAMINATIONS MADE AT PIVOT PIER, LITTLE ROCK JUNCTION BRIDGE, MO. PAC. RAILWAY.

"*South Corner.*—Depth of water, 28 ft. 11 in. below low-water surface. Depth of rock, 35 ft. 6 in. below low-water surface. Drilled into rock 4½ in.

"The pipe was driven through fine sand, followed by a layer of coarse white sand mixed with black scales, feeling and looking like graphite; immediately overlying the rock was found a layer of fine and coarse gravel mixed with coarse sand. The rock is commonly called slate, is a black shale, which yields readily to the drill. Time occupied in setting and sinking pipe about 3½ hours.

"*East Corner.*—Depth of water, 13 ft. 6 in. below low-water surface. Depth of rock, 37 ft. 6 in. below low-water surface. Drilled into rock 3 in.

"The pipe was easily driven in medium sand, passing into sand mixed with gravel to a depth of 23 ft. below low water. This continued to a depth of 30 ft., where sand and gravel mixed with a soft but tenacious clay was found. At 34 ft. down a rather fine sand was found, mixed with clay. Rock was reached at 37 ft. 6 in. below low-water surface. There was found no well-defined stratum of gravel at this corner. The rock was of the general character, as already indicated. Time occupied in sinking about 4 hours.

"*North Corner.*—Depth of water, 22 ft. 7 in. below low-water surface. Depth of rock, 39 ft. below low-water surface. Drilled into rock 3½ in.

"Pipe was easily driven through medium sand to a depth of 29 ft. 3 in. below low water. At 26 ft. 9 in. was found fine and coarse sand mixed with fine and coarse gravel, and black scales, which continued for about 2 ft. to a depth of 28 ft. 9 in., the driving being somewhat difficult to a depth of 30 ft. 9 in., below this the pipe entered a fine flowing sand, which rapidly filled up the pipe for several feet whenever the jet was stopped. This material consisted of fine white sand, suggesting quicksand by its readiness to flow. From this point it was necessary to run hammer and jet simultaneously. The large pipe followed the small pipe readily, but would fill up if jet stopped. This fine sand continued to a depth of 39 ft. Drilled into the rock about 3 ft. Rock similar to that at other places. Time about as at other points.

"*West Corner.*—At and near this corner large quantities of rip-rap have been deposited. It was impracticable to find an opening through this sufficiently large to permit the passage of the 3-in. pipe. The small jet pipe was easily run to a depth of 33 ft. 6 in. below low-water surface. Further progress was prevented by a bed of gravel and the friction on the pipe above. Several attempts were made to force the 3-in. pipe through the rip-rap, which invariably resulted in the squeezing and mashing of the large pipe and the parting of the small pipe. On Saturday, March 12th, however, we succeeded in getting the 3-in. pipe through the rip-rap.

"Depth of water 19 ft. 3 in. below low-water surface.

"At 24 ft. down, the pipe brought up on a log. This log was bored through, it proving to be 12 in. thick. The timber was found to be firm and sound. The 3-in. pipe was driven through this log, and at 26 ft. 10 in. the pipe struck another log, which was partly bored through, when further work was stopped at 6 P. M. It had been raining hard all day, which continued through the night. The river rose rapidly, so much so that it was necessary to remove the barge to a place of safety. Work in the river was then abandoned for one week. This ended the first week's work. There were many delays, caused by time required to cut and thread pipes, and pump getting out of order, foaming of the boiler, etc. These were, no doubt, incident to and unavoidable in this kind of work, and it is not intended to attach any blame to any one, as all parties seemed disposed to do anything when called upon, and on the whole I was entirely satisfied with the work done the first week.

"Seeing no prospect of getting to work in the river, preparations were made to get into the crib within the well in the center of the pier, and on Thursday, March 17th, work was commenced. The well was found to be filled to about 11 ft. with silt, logs, and stone. After several efforts, a 3-in. pipe was forced to the timbers of the deck, and these timbers, about 2¼ in. thick, were bored through, admitting the small pipe without difficulty several feet below the deck and into the filling of the crib. This filling proved to be small stone, sand, and gravel. In attempting to drill through a stone the small pipe parted, resulting in loss of drill.

"On Monday, March 21st, the river having fallen a few feet, an effort was made to resume work in the river. A large portion of the day was consumed in getting the barge in position, and little was done subsequently, owing to the almost continuous foaming of the boiler, and consequent failure to supply requisite pressure. On Tuesday, with a rising river, a new pipe was sunk near the west corner, but it could not stand the constant vibrations caused by a strong current acting on some 40 ft. of unsupported length, and broke. At this

time the river had risen considerably, and it was deemed necessary to remove the barge to a place of safety.

"I desire to express my appreciation of the uniform kindness, consideration and faithfulness of officers and laborers on this work.

"With great respect,

"W. M. PATTON."

SPECIFICATIONS FOR THE CONSTRUCTION AND SINKING OF CAISSONS FOR THE PURPOSE OF REPAIRING THE PIVOT PIER AND PIER 4 OF THE LITTLE ROCK JUNCTION BRIDGE, MISSOURI PACIFIC RAILWAY.

"There will be constructed two caissons, the one for the pivot pier and the other for Pier 4. These caissons may be of such design and dimensions as will entirely surround the old piers of the bridge or will extend around any portion of these piers, as may be directed by the Engineer of B. & B. of the Mo. Pac. Ry. These caissons shall be constructed according to designs given on Sheets 1, 2, and 3 accompanying and forming a component part of these specifications, or according to such other design as may be accepted or approved by said Engineer of the Railway Company.

"Sheets 1, 2, and 3 give plan, elevation, section, and exterior and interior detail of the caisson and coffer-dam to be constructed entirely around the pivot pier.

"The structure is built of timber and iron; all timbers are 12 by 12 in. in cross-sections, excepting a few pieces 9 by 12 in. and 6 by 12 in., used for supporting braces, and 3-in. planks necessary for lining the caisson and coffer-dam. Exact lengths are given and where not given variable lengths are allowed. All necessary dimensions are given on the drawing and require no description. In the event that Engineer determines to construct a caisson of only one-half the dimensions given in the plan, no change in design will be required except closing up the free ends as indicated in the drawing.

"*Timber.*—All timbers used in the construction of the caisson and coffer-dam may be what is known as merchantable, and may be either pine or oak. *The outside verticals forming the lower half of the structure must be of the best long-leaf yellow pine and showing clear heart on the exposed face.* All timbers must be free from all defects that will impair their strength, such as rot, dotiness, or sponginess, large knots, or deep shake, or cracks of any kind. All framing and fitting must be done in a workmanlike manner and to the approval of the said Engineer.

"The upper and lower halves of the structures are to be built entirely independently and not bolted together in any manner. The two halves being held together solely by the 1¼-in. hook-rods, as indicated in the drawings. The lining plank in the caissons, as well as

in the coffer-dam, shall be planed on the edges for a caulking joint.

Caulking.—The caulking of the inner plank of the air or working chamber shall be thoroughly done, so as to make the sides and top of the air chamber completely air-tight and paved over with tar or pitch. Oakum shall alone be used in caulking. The joints of the top deck course shall also be sufficiently caulked to form a water-tight surface. The verticals forming the sides of the caisson, or lower half of the structure, shall be caulked on the outside, so as to form a water-tight surface. The inner plank lining of the coffer-dam shall be caulked, so as to make water-tight surfaces, as reliance for keeping out water is placed entirely on this caulking.

"*General Construction.*—The exposed surfaces of the lower half of the structure are built of timbers 12 by 12 in. by 23 ft., thoroughly bolted to these on the inside are five layers of horizontal timber, one layer on top of the other, which are well bolted to each other; spiked to these horizontal timbers are two layers of 3-in. plank, the first course placed diagonally and the second or inner vertical and caulked. Resting on top of the horizontals and plank, is placed a solid layer of 12 by 12-in. timbers, bolted at the ends to the horizontals; on top of this another solid layer of 12 by 12-in. timbers, placed diagonally and bolted at intervals of about 5 ft. to the first course, with 1-in. square by 22-in. drift-bolts. Over this course another solid course of 12 by 12-in. timbers laid longitudinally and similarly bolted to the course below. These three courses constitute the deck of the caisson proper. To the underside of this deck a layer of 3-in. plank is spiked and caulked. Above the deck and between the vertical sides, an open crib of 5 courses of timber is constructed, bolted to the verticals, to the deck and to each other. Above the crib is one set of cross-braces between the verticals and resting on longitudinals, bolted to the verticals. Diagonal rods are used in spaces between these braces and in a horizontal plane. Another set of cross-braces are placed at the top of the outside verticals. This completes the lower half of the structure and may be denominated as the caisson.

"*Coffer-Dam.*—Sills are placed on top of the verticals on both walls of the caisson, and upon the sills, at a general interval of 5 ft., center to center, vertical posts 12 by 12 in. by 21 ft. are placed, and on top of these posts caps are placed. These posts may be spiked or bolted to caps and sills, or they may be mortised and tenoned. Two layers of 3-in. plank are then spiked to caps, sills, and posts on the inside. The first layer is placed diagonally and the second or inner layer horizontally and caulked.

"Cross-pieces are then placed over the caps and projecting 18 in. beyond outside verticals, through which the 1¼-in. rods with hooks, pass. These rods are connected with the I-bolts, let into the verticals. Plate washers are used at the top, as the two halves, upper and lower,

are to be pulled and held together by these hook-rods. The two joints between sills and top of the verticals of the caisson are to be well caulked after the two portions are pulled firmly together. An inner strap, countersunk, encircles the caisson, to which it is well spiked just above and resting against the I-bolts. There are three sets of braces between the walls of the coffer-dam, with diagonal rods between them and horizontal planes, as indicated in the plan and sections. These rods have swivels or couples at some intermediate position.

"The coffer-dam is framed in four sections, two of which are 70 ft. long and two are 44 ft. long. These sections are connected at the ends by diagonal rods with swivels and couplings, double posts being used at the junction of the sections; also 18-in. channels are let into, but not bolted to, these posts, in order to hold the sections together.

"Removing these channel irons and uncoupling the diagonal rods, sever all connections between the sections of the coffer-dam as well as the two walls of the same section, so that the upper half of the structure can be readily removed at the completion of the work. The lower half of the structure is intended to remain permanently in place. All other details, with bolts, straps, and braces, are shown on the drawings, and also the dimensions of the same, as well as the bill of material accompanying.

"*Iron.*—All iron is to be good, tough, ductile, and fibrous, except that all washers may be cast iron. The top washers for 1¼-in. hook-rods should be wrought-iron plate, about 1 by 6 by 6 in. In all cases the grip of screw bolts, that is, net length of washers, is billed. Proper allowance must be made for heads, nuts, and washers. The weights given are for full lengths, including heads, nuts, and washers. All bolts must be wrapped with oakum under head before driving, and at the threaded ends before placing nut and washer on.

"All drift-bolts are billed as 1 in. square. Round drifts 1 in. in. diameter may be substituted, except for those bolts used in the outside verticals of the caisson.

"*Filling Material in Caisson and Coffer-Dams.*—All these caissons are only used for a temporary purpose and for convenience and certainty, and, after being sunk to the proper depth, serve only the purpose of coffer-dam, the material used in the filling is of secondary importance. The filling in the coffer-dam is only required to give weight necessary to sink the caisson and may therefore be any material. As far as practicable, the material taken out of the working chamber may be deposited above the deck of the caisson and in the coffer-dam, thus furnishing weight to sink the caisson. Also the material between the old caisson and new caisson may be excavated by dredging and likewise deposited in the coffer-dam, care being taken, however, not to remove the material at and near the west corner of the old caisson until it is safely secured by permanent supports, or

temporary supports, from further settling. It may not be necessary to entirely fill the coffer-dam in order to secure sufficient weight. If necessary or desirable, water may be let into the coffer-dam so as to supplement the weight of other material, in such case, the water can be ultimately pumped out, thus facilitating the removal of the coffer-dam.

"The filling in the working chamber of the caisson after it has reached the rock, or its final position, is only necessary to prevent leaking under the caisson. It must be such material, and in such quantity, and so placed as to prevent any under flow of water. No filling of any kind may be necessary, and will not be if the water surrounding the old caisson and between it and the new caisson can be pumped out and kept out. In this case some additional cross-bracing in the working chamber may be found necessary. It may be found necessary to fill the working chamber in the whole or in part with clay puddle, a water-tight joint between the caisson and rock being the important object.

"*Excavating the Material Between the Old and New Caissons.*—This may or shall be done in part during the sinking of the caisson, and the material thus excavated used to weight the caisson. In any event, the material at and near the west corner of the old caisson must not be disturbed or removed until a sufficient and safe support has been placed at other portions of the caisson. The material at and near the west corner can then be removed, thus exposing the entire surface of the old crib and caisson from its top to rock.

"*Raising or Leveling the Old Caisson.*—It is the intention of the Railway Company to lift and return the pier to its original and proper position, for which purpose the use of hydraulic jacks will be necessary. It will be necessary for this purpose, or at any rate may be advisable, to support the superstructure on trestles or some other form of temporary supports. The posts of the coffer-dam should not be used for this purpose. However, a sufficient number of additional posts may be inserted in the coffer-dam to carry the load. It will be better and safer, however, to support the superstructure by supports entirely independent of the coffer-dam.

"After inserting the jacks, with proper and safe bearing for uniform distribution of pressure, it may be found necessary to flood the coffer-dam, thereby reducing the weight to be lifted. In this case the pumps will have to be above the water surface and connected by means of small pipes to the main cylinders of the jacks. An additional number of jacks should be provided, and as the water is again pumped out, these should be brought into bearing so as to support the extra weight brought into action when the water is removed.

"In the event of constructing a caisson entirely around the old structure, it may be easier to excavate the rock from the south corner around through the east corner and as far as may be necessary toward

the north corner, and to level the structure by lowering the high portion of the caisson, rather than by raising the lower portion by means of hydraulic jacks.

"*Filling Under Old Caisson.*—In whatever manner the old caisson is restored to its proper position, or whether it is left in its present position, all loose material is to be removed from beneath the old caisson and good Portland cement concrete substituted. The concrete shall be composed of such material, mixed in such manner and placed and rammed in accordance with the approval and direction of the said Engineer of the Railway Company. Unless the structure is safely and securely supported by jacks, this work of underpinning must be done in sections, so as at no time to endanger the structure by further settling at any point. The jacks, if used, must be left in position until in the judgment of the Engineer the concrete has been sufficiently hardened to be able to carry the load with safety. The jacks can then be removed and the spaces filled with concrete, if the Engineer may so require.

"*Refilling Between Old and New Caisson.*—The space between the old and new caisson, from the rock to the bed of the river, will be refilled with material, if so required by the Engineer.

"*Removing the Coffer-Dam.*—The upper half or section of the structure, known as the coffer-dam, will be removed as already indicated.

"*General Remarks.*—In the bill of iron no mention is made of shafts, pipes, or other appliances required to sink the caisson, as these are regarded as belonging to the contractor's plant.

"The contractor shall furnish all material, tools, machinery, and apparatus of all kinds required to construct and sink the caisson, pump out water, and remove material. The contractor shall be responsible for any damage to the old structure, and shall take all risks incident to such work. The Railway Company shall be in no wise responsible for loss of life, damage to property, or interference with the safe navigation of the river. He will be responsible for all acts of his employees, and shall discharge any of his employees, when so directed by the Engineer, who fail or refuse to perform the work in accordance with the direction of the Engineer or his duly authorized representative.

"All material is to be approved and accepted by the Engineer before being used in the work. All work must be done in a thorough and workmanlike manner and to the approval of the Engineer or his duly authorized representative.

"*The Caisson for the Pivot Pier.*—The caisson for the pivot pier is composed of four sections; two of these are 70 by 13 ft. in plan and the other two are 44 by 13 ft., when the caisson entirely surrounds the old caisson. If it is determined to enclose only one-half of the old caisson, only three sections will be required: one 70 by 13 ft.;

and two 38 by 13 ft. All sections are 46 ft. 3 in. from bottom of caisson to top of coffer-dam, and 47 ft. 3 in. over all. Estimated cost on first plan $40 000, and on second $21 200.

"*The Caisson for Pier 4.*—The caisson for Pier 4 is composed of four sections; two of these are 70 by 13 ft. in plan and two are 27 by 13 ft., when the caisson entirely surrounds the old caisson. If it is determined to enclose only one-half of the old caisson, only three sections will be required, one 27 by 13 ft. and two 35 by 13 ft.; all sections are 46 ft. 3 in. from bottom of caissons to top of coffer-dam and 47 ft. 3 in. over all. Estimated cost on first plan $34 000, and on second $17 000.

"In either case the designs are essentially and substantially the same, only differing in axial length."

APPENDIX B

LETTERS OF A. J. TULLOCK ACCOMPANYING BID OF MISSOURI VALLEY BRIDGE AND IRON COMPANY FOR CARRYING OUT PATTON'S RECOMMENDATIONS AT PIVOT PIER AND PIER 4.

"LEAVENWORTH, KAN., Aug. 17, 1898.

"MR. E. FISHER,

"Engineer B. & B., Mo. Pac. Ry.,

"Pacific, Mo.

"DEAR SIR: Referring to your claims and specifications for the repairs of Piers 2 and 4 of the Little Rock Junction Railway Bridge, will say that I have gone into that subject quite fully and submit you herewith three separate propositions, covering the main portion of the work to be done in said repairs, leaving, however, certain parts of the work, the nature of which cannot now be determined, to be arranged at a later date when it can be clearly seen what is required. Such work can very well be done on a percentage basis, and probably so to best advantage.

"It is quite clear that the settling of the piers mentioned in the Little Rock Bridge arises either from the caissons not having been originally properly founded in solid rock, or from the crushing of the timbers in the cribs between the caissons and the masonry, as it is well known that these cribs were not well constructed when the work was built. Present appearances would indicate settlement due to the caissons not having been properly founded in the solid rock, rather than to the crushing of the cribs, but as against that, we have the written statements of the contractor who built the work, Mr. Barr, and of the Resident Engineer in charge of the work, Mr. Purdon, both reputable gentlemen, both of whom agree in saying that the caissons were properly founded in bed-rock and that the settlement of these two masonry piers must be due to crushing of the cribs. However, this can only be satisfactorily determined by actual examination, after sinking outside surrounding caissons as is now proposed.

"From a careful reading of your specifications, I conclude that, inasmuch as no concrete or filling of any kind is required in the caissons, that it was the intention of Prof. Patton that these caissons should be used simply for the purpose of getting down into the rock around the old piers to permit the underpinning or other repairs suggested by him, and that he contemplated relying entirely upon the underpinning or repairs made directly in the body of the old piers for permanent stability.

"It seems to me that we cannot safely rely on such underpinning for safety in this case, and it is very doubtful indeed if such underpinning can be done at all, without greatly endangering the entire

structure of the old piers. It is my opinion that the work to be done in this case should properly consist of sinking the caissons as proposed in your specifications, but that they should be filled with some material sufficient to provide permanent lateral stability, and that the space between the new caissons and the old piers should be excavated down to bed-rock, pumped out, and filled with concrete to a sufficient height to thoroughly support the old pier and prevent any lateral movement. This being done, and the outer caisson being sunk into rock so as to absolutely shut off any outward movement of soft material, which may underlie your present pier, the absolute stability of the pier against further settlement or movement of any kind will undoubtedly be assured, providing this settlement is due to lack of perfect foundation under the original caissons. I have therefore arranged my proposals with a view of carrying out this plan, as well as making them applicable to the programme apparently contemplated in your specifications, in case when the excavations are made, it might be found possible to make the repairs as suggested by Prof. Patton.

"I will not hesitate to say in advance, however, that I consider the method of repairing proposed entirely impracticable, and too dangerous to warrant its adoption, except under conditions so extremely favorable that we have no right to assume they will exist in this case.

"The caissons necessary to surround these old piers properly are necessarily so unusually large as to become very expensive as compared with the ordinary caissons used underneath piers of that kind in original construction, and in addition to the fact that a very large volume of material, both in construction and excavation, is involved, the peculiar form of these caissons is such that they must be very strongly constructed and braced in all directions to prevent danger of their becoming twisted in sinking, and being wrecked in that way. The cost of these caissons in place, therefore, becomes very much larger in proportion than the cost of ordinary caissons for new piers.

"We have figured out these caissons in detail, and submit you herewith blue prints of same, numbered respectively 3 928 and 3 929.

"I submit the following proposals for doing this work:

"*Case 1.*—This case includes furnishing, building, and sinking to the depth specified by you, the timber caissons and coffer-dams described in your specifications, and shown on our drawings, including the excavation of all material within the caissons to such specified depth, and the excavation and pumping out of the material between the new caissons and the old piers down to bed-rock, providing it can be excavated that far without endangering the old piers. This case, however, does not include the filling of any of the caissons with concrete.

"Furnishing, building, and sinking as above described,

"Pier 2 (draw pier)..... $28 600.

Furnishing, building, and sinking Pier 4... 25 600.

"*Case 2.*—Caissons and coffer-dam constructed and sunk precisely the same as in Case 1, and all necessary excavation same as in said case, adding thereto, however, the sealing of the caissons in the working chambers with Portland cement concrete to a height of 2 ft. above the cutting edge, all the way around, and remainder of the working chambers and caissons to be filled with pure sand:

"Pier 2, as above described.....$31 600.
Pier 4, as above described..... 27 950.

"Steel caissons 6 ft. wide in the clear, height same as for wooden caissons, Cases 1 and 2, surmounted by wooden coffer-dams as in Cases 1 and 2—these caissons to be sunk to the same depth as the others and to have the entire working chambers of same filled with Louisville cement concrete, the remainder of the caissons to be filled with sand. Excavation between caissons and piers same as in Cases 1 and 2. This case presents some advantages and would perhaps be preferable to the wooden caissons, but for the fact that it may be practically impossible at the present time to get the plates necessary to construct these caissons of steel quickly enough to insure the work being done within the low-water period in the river. I have only considered this case within the past 24 hours, and am therefore unable to submit you a complete drawing of the steel caissons, but hand you herewith a pencil sketch which will serve the purpose of showing the construction contemplated. This caisson being only 6 ft. in width at the bottom, while the wooden caisson is 12 by 13 ft., it will serve the same purpose so far as shutting off the outflow of material from underneath the old pier is concerned, but not having so wide a base, it has been considered best to fill the entire working chamber of these caissons with concrete, whereas in the other case, with the wider base, we can probably, with perfect safety, use part concrete and part sand as described in Case 2.

"Pier 2, as above described.....$30 770.
Pier 4, as above described..... 26 655.

"In connection with this work, I will furnish and put in place the concrete filling required for the spaces between the new caissons and the old piers, at the following prices per yard:

"For Louisville cement concrete.....$4.85
For Portland cement concrete..... 7.38

"In all of the concrete work herein contemplated, the proportions for mixing are assumed at 1, 2, and 4 for Louisville cement concrete, and 1, 3, and 6 for imported Portland cement concrete. The quality of Portland cement assumed to be equal to Alsen's German.

"In this connection, I wish to say that we have a plant on hand ready to do this work, and could commence it immediately, our plant being now idle at Jefferson City, Mo. I will be glad to do any extra

work that may be required, not covered by these proposals, on a basis of cost plus 10%, including, of course, the equipment costs as well as labor costs.

"For the purpose of comparison, and illustrating the expensive character of the repair work contemplated on these two piers of your bridge, will say that I should be glad to furnish all material and build an entire new set of piers for that bridge according to the best modern specifications and practice, for the sum of $125 000.

"Very respectfully submitted,

"A. J. TULLOCK."

"LEAVENWORTH, KANS., Aug. 18, 1898.

"MR. E. FISHER,
"Engineer, B. & B., Mo. Pac. Ry.,
"Pacific, Mo.

"DEAR SIR: Referring to the caissons for the repair work of your piers at Little Rock, we figure the cost for sinking the extra depth on these caissons, assuming that they are to go through bed-rock, at about $800 per foot for the large caissons for Pier 2 and about $750 per foot for the smaller caissons Pier 4. We assume, of course, that if this extra depth is required, that the excavation will be practically all solid rock, which makes the cost run up quite high. I have to-day carefully examined the record of the borings made by ourselves a few years ago, and also those made as reported in your specifications, and I feel quite certain that the depth you have specified will prove to be about right, and that no extra depth will be required. Certainly none will be required, unless we should strike a fissure in the rock, which it would be necessary to shut off, and even then in that event, we could probably clean it out and plug it with concrete inside the caisson much cheaper than sinking the whole caisson farther down. In figuring the cost of the entire work, we have distributed the plant charge, machinery, repairs, maintenance, use of plant, and all charges of that kind over the depth specified, and as this charge would remain the same, or practically the same, for a less depth, the saving for sinking less than the depth specified would not be a great deal, particularly if we assume that down to that depth only a portion of the excavation is rock. We figure, therefore, that the saving, in case we do not go as deep as specified, would be about half the price named per foot for extra depth.

"The price which we name for extra depth would only apply for a depth of 5 ft. below the depth specified in your specification. For any further depth, there will be an increase of about 50 per cent. This increase for extra depth is partly due to the fact that the schedule of wages paid the pressure men or "sand hog" increases for every foot below 20 ft.

"In reference to completion of the work, we would expect to complete the entire work in four months, providing we receive the order for it immediately, and I will undertake to do it in that time, barring accidents or floods or any such things as would be beyond the control of the Contractor. I feel certain, however, that nothing is likely to occur that would stand in the way of the entire completion of the work in about four months, and we have made our figures on that basis. If it took much longer than that time, we would be the principal losers, as the cost would increase very fast by the extra time used.

"In going over the figures on this work to-day carefully, I find that we have made them exceedingly close, and if we do that work, we should want to know at once about it, or within the next few days at farthest. I shall be glad, therefore, if you will reach a conclusion as soon as possible and notify us.

"Yours truly,

"A. J. TULLOCK.
"Proprietor."

"LEAVENWORTH, KANS., Aug. 19, 1898.

"MR. E. FISHER,
"Engineer, B. & B., Mo. Pac. Ry.,
"Pacific, Mo.

"DEAR SIR: I have your favor of the 17th inst. with reference to modifying the dimensions on caissons for repairing the piers of your Little Rock Bridge, and have carefully noted what you say. I hardly think that it would do to figure on reducing the size of these caissons, nor do I think it would be desirable to do so. In the first place, we have no greater width between the caisson and the pier than is necessary to properly support the pier. In the second place, we cannot very well work closer to the old pier safely than 6 ft., as by getting much closer we would be likely to encounter more serious difficulties than are now contemplated and add to the cost. Further, in caissons of this character, on account of being so unwieldy and difficult to handle, it is not likely that they can be kept in exact position; in other words, the caisson is liable to be from 6 to 12 in. out of position in almost any direction, and this perhaps cannot be avoided. Of course, we will endeavor to keep it in position, or if out of position at all, to have the greatest distance between caisson and pier on the side to which the pier leans, so as to have the heaviest supporting wall on that side. We might save some caisson material by cutting down the dimensions of the caissons a little, but we would at the same time, increase the cost per unit quantity in certain parts of the work, so that on the whole there would not be much saving. It will be a difficult job at best to keep the wooden caissons of that character from racking to pieces on account of uneven support, even with a width of 12 or 13 ft., and

the more we reduce its width the greater this difficulty becomes. So far as the caisson itself is concerned, and as to the opening between the caisson and the old pier, if we get much closer to the pier than we have figured, we will increase the cost of sinking more than the saving made in caisson material by reducing its exterior dimensions.

"In the case of the Kansas City draw-pier, where this plan was followed with a circular caisson constructed of steel, the caisson was brought closer to the pier than in your case, being only 3 or 4 ft. from it, but in sinking that caisson, the average progress per day was from 3 to 5 in. for each day of 24 hours, and the entire cost for that pier was between $40 000 and $50 000, being somewhere close to the latter sum. We have studied the subject quite thoroughly and carefully from an engineering standpoint, and also from a practical standpoint with Foreman Stewart, who has had large experience in such work, and it seems to me that we have hit upon the best construction for the place at the least possible cost. I realize fully that this is a good deal of money to put on repairing two old piers, but I do not see any way to better the situation unless you should decide to put in entire new piers throughout the whole bridge, and in answer to your inquiries about that project, will say that the price I gave you of $125 000 for replacing the entire piers contemplated putting the further pier on the Argenta side on piles, which could probably be safely done. However, we could make that pier a pneumatic pier also putting it down to rock, by increasing the cost to $135 000, or thereabouts, and of course in these new piers we would not expect to use Cabin Creek stone except for backing, the face stone to be strictly first-class masonry, both in quality of stone and workmanship, instead of cheap rubble, as in the case with the present old piers of that bridge.

"I find that I shall probably have to be in Chicago on Monday on some bridge business for the Santa Fe, but can be in St. Louis Tuesday, or if you wish to take up the subject Monday and could wire me to-morrow, I might postpone my Chicago business until Tuesday. Should you decide to have us do this work, I would thank you to have Mr. Spoor, your Timber Agent, give me the names and addresses of the mills which could furnish this timber quickest and best, as it would be necessary to move at once in the matter of getting timber and equipment on the ground in order to be sure of getting the work done before there is danger of high water.

"Very truly yours,

"A. J. TULLOCK.
"Proprietor."

APPENDIX C

LETTERS OF A. J. TULLOCK, WHILE CARRYING OUT WORK RECOMMENDED BY PATTON.

"ST. LOUIS, November 24, 1898.

"E. FISHER, ESQ.,
"Engineer, B. & B., Missouri Pacific Railway,
"Pacific, Missouri.

"DEAR SIR: We have the caisson of the center pier built up about 8 or 10 ft., and last night we placed the second course of decking on the caisson. It is already lowered, so that one-third of its weight is taken up by water displacement, thus relieving the lower screws and supporting piles. We are, therefore, safely past one state of danger, which arose from the fact that our piles did not have much penetration and being difficult to brace. The matter of supporting so large a caisson on lowering screws was naturally a deal of a problem and somewhat risky. We feel, however, that we are now safely past any danger from the trestle support, and we shall, within the next two days, unless something unexpected interferes, have the caisson resting entirely on water and the screws relieved and removed to Pier 4. As soon as the screws can be set up on Pier 4, we will proceed with the building of the caisson, while we continue the sinking of the caisson at Pier 2. As near as I can tell, we should have air in the caisson of Pier 2 in about ten days or two weeks at the farthest. This, however, depending somewhat upon how much trouble we have in getting a proper bearing for this large caisson on the bed of the river. You will readily understand from the shape of this caisson in its unusual dimensions, that it becomes very necessary to handle it gently and lay it on the bottom in a good and reasonable uniform support, in order to prevent it from being strained and the joints opened so that it will not serve its purpose. Very little irregularity of support when the caisson commences to be loaded would likely spring it badly, notwithstanding the fact that we have built it unusually strong. It, therefore, becomes very important to get it carefully landed and this is our next critical movement. The fact that the sand has all been scoured away from that pier, which we did not expect, increases this difficulty very greatly, and it is impossible to make a fill around the pier by wing-dams above, as there is not enough material carried by the water at present to make such a deposit practicable. We have to depend, therefore, upon leveling off as much as we can before resting the caisson on the bottom, and then using sacks of sand for building up underneath the cutting edge of the caisson for support at the low points, and with this in view, I have already shipped several thousand coffee sacks from St. Louis to Little Rock so as to be in readiness. Superintendent

Stewart has the work well in hand and understands thoroughly every move to be made and every emergency likely to be met with.

"We are now approaching a time on this work when we must think carefully about what you are going to do when these caissons are down in position and the excavations made between the new caissons and the old piers. Of course, you cannot tell exactly until these excavations are made, but you must contemplate to some extent in advance, what material will be required, so that this material, such as Louisville cement and crushed rock, can be procured, on hand ready for use. You will recollect that while our contract provides a price for the concrete filling of this area between the new caisson and the old pier, the work of so doing is left for later determination. Therefore, I have provided no materials for such filling, and can only do so on your order. I would suggest that you authorize me to procure a certain amount of Louisville cement and crushed rock, which you think will safely be needed, immediately, so as to have it on hand when we are ready for it. You can certainly approximate the minimum quantity needed, and it is more than likely that you will want to fill this whole area as far as possible with concrete, in order to get the best results. Now, while it is important for the Contractor, on account of the coffer-dam and caisson and danger of floods in the river, that this work should be dispatched very rapidly after the excavation is made, it is still more important for the Railway Company and the owners of the old bridge that the structure should not be left exposed a *single hour longer than is absolutely necessary after this excavation is made.* There are abundant reasons for this, which you will doubtless recognize at once, and I now only mention one or two of them. In the first place, that old pier, caisson, and crib was so poorly constructed at the beginning that even if it were in as good condition as when first built, it would be very bad judgment to allow it to remain any length of time with the material all excavated away from it, as we are required to excavate. There is always danger in such performance of something of the unexpected happening, even if the pier stands perfectly square and true and is well built. Again, the timbers in that old caisson and crib, which are rough hewn timbers, improperly framed and about half enough in quantity, have now been soaking in the river about 14 or 15 years, and there is no telling what effect exposure to the air, for even two or three days, might have on these old timbers, heavily loaded as they are, without being reinforced by any interior filling of concrete or any other material of value. It has probably come to your notice that certain kinds of timber long submerged in water when taken to the surface, apparently in excellent condition, come to pieces very quickly after exposure to the air. I do not know that there is any danger to the timbers of these old piers, but at the same time it is possible that there may be and it is a matter

worth thinking about. So on the whole, it is undoubtedly the best policy to be ready to act quickly when the excavation is made, and to get the filling with concrete made around the old pier as high as possible and within the shortest possible time after the excavation is made.

"In the case of Pier 4, I have a suspicion that that pier is already taking a good deal of its lateral support from the material, sand, etc., which now surrounds the old crib and caisson. It is possible that it may be held directly in position by this material, which you will notice extends up quite high in that pier. This being the case, we will have to proceed very carefully indeed with our excavation, both in sinking the caisson and in making the excavation between the new caisson and the old pier, as that portion will necessarily be attended with a great deal of danger, and conditions may be discovered as the work progresses, particularly with reference to the excavation between the caisson and the pier, which would make it necessary to change your plan of operations materially. I mention this now only that you may be thinking about it in advance, as I have been for some time past.

"In this connection, you will see at once the necessity of having very frequent observations taken as to the movements of these piers from the time we commence excavating, even in the new caissons alone, until we are through with the work. It is altogether likely that at certain stages of the work, it will be necessary to take these observations several times a day, and even almost hourly, so that any movement whatever of the old piers will be detected and made known to our men in charge. I mention this now so you will make arrangements with your Assistant Engineer, who has been taking these observations, to be present on the work when our excavations commence, ready to report promptly any appreciable movement of the piers. I do not anticipate any movement of consequence at the center pier (Pier 2) but of course that depends on what we may find the conditions to be underneath. I have a young office engineer, Mr. St. John, on the ground, who has experience in the use of field instruments, and I shall be glad to have him assist your engineer in taking these observations when the time arrives. Please let me know in good time if you will arrange to have your engineer present to look after this matter during our excavations. It is important that this matter should receive careful and accurate attention. Write me at Leavenworth.

"Very truly yours,

"A. J. TULLOCK."

"MR. E. FISHER, "MAY 16, 1899.
"Engineer, B. & B., Missouri Pacific Railway,
"Pacific, Mo.

"DEAR SIR: Your favor of May 6th, written at Little Rock, Ark., was duly received during my late absence. I note your instructions in

reference to the work remaining to be done at Pier 4, that is, the concrete filling, etc., I believe the plan which you propose, which is substantially that adopted at Pier 2, is a very good one, and will get the best results with the least possible expense. I think the idea of supporting the old crib as high up as possible with concrete, as we have done at Pier 2, is the best solution of this difficulty, and I also believe that the material below the concrete, if of a reasonably substantial character, such as sand or rip-rap, is equally good when covered with a sufficient amount of concrete on top, which permits you to give the desired support to the old crib, and pier with the use of a minimum amount of concrete, much less in fact, than was originally contemplated. We will, therefore, probably have considerable extra cement left on hand, which your Company can no doubt dispose of or use to advantage.

"I note what you say in regard to pumping down and excavating between the coffer-dam and the old crib, and in reply will say that I will be glad to pump down and excavate just so far as it is practicable to do, but cannot undertake to go farther. This is precisely the conditions of our contract, and you no doubt fully realize that any attempt to do more than is practicable to be done in this case, would not only be a needless waste, not contemplated, but might also, particularly in the case of Pier 4, greatly endanger that pier. You will recollect further that when you had plans and specifications prepared for this work by some eastern professor or school teacher, your specifications provided for doing a whole lot of theoretical experimental work which was absolutely absurd, and which could not possibly have been carried out under any condition. I called your attention to this at the time, and I think that you agreed with me at that time in reference to it, and I suggested the present plan of work in my proposal, which was adopted. When the contract was drawn by your attorney, which was done during my absence and afterward presented to me for signature, I called attention to the fact that in drawing it, your attorney had provided for what was probably impossible, explaining that it would probably be impracticable to do certain work which seemed to be contemplated in the contract, the character of which was somewhat the same as you had in the professor's original specifications. Your attorney then modified his language in the contract by adopting my own expression in regard to pumping and excavating, which was that we should do just so much as was practicable to be done. Now this is the meaning of our contract, and I wish to make it clear to you, as you seem in your letter to want to swing a club over the head of your contractor, by talking about compelling him to pump down below the cutting edge of the old crib and caisson and do certain other impossible and absurd things, and you know very well that there is no object whatever in doing this, even if

it could be done, and if that material, which is in this case mostly all rip-rap stone, could be taken out, you would simply have to put it back again to give the necessary support to the pier or to substitute concrete in its place, which would cost your company several thousand dollars more than the present arrangement and would be practically no better. Furthermore, you must be aware that the inclination of Pier 4 is so severe to one side that it would be extremely dangerous and inviting disaster to excavate that material between the new caisson and the old crib to any great depth. This is all clearly manifest. I am writing you thus fully as I wish to make my views clear on the subject and wish to put them on record. In sinking the caisson around Pier 4 we went down as you know on all sides through rip-rap most of the way. There was a little less rip-rap on the down-stream side of the pier than on the up-stream side, but nearly all the filling, at least, the main mass of the material around the old crib and between it and the coffer-dam, is now rip-rap, and by putting a good solid bed of concrete on top of it, you will have supported that pier in the best possible manner, as with the new caisson in position it cannot get away.

"I dislike very much to complain, but I must say that the whole tenor of your demands and instructions seems to be of the nature of threats of putting your contractor to unwarranted costs and expense rather than for the purpose of getting the best results on work or of giving any special benefit to the job or your company. You seem to lose sight entirely of the dangerous and costly nature of the work we have to perform around these two piers successfully, and of the great cost and heavy loss which has been sustained in carrying out this work safely. You seem to be looking only for a chance to put your contractor to needless and foolish expense of one or two hundred dollars in doing something which you imagine you have a right to demand, whether it is any value to the work or not, and to entirely ignore the fact that in sinking these tremendous large caissons around your old piers through rip-rap, piles and everything else, and through a large amount of solid rock, we have been compelled to proceed so slowly in order to avoid injuring your old piers, that the cost of doing the work has been double what was contemplated.

"I note that you say in your letter 'before concrete is put in, the depth of the cutting edge must be determined.' Now, when we have pumped down between the coffer-dam and the old crib of Pier 4 and have gotten that crib ready for concreting, we must be ready to concrete at once and finish quickly, as it will be dangerous and absurd to endeavor to hold that pumped out coffer-dam against chances of rises in the river and other disasters any length of time, for a foolish effort to try and determine the depth of the cutting edge of the old caisson. At best, the determining of the elevation of this cutting edge is only to gratify a curiosity and can serve no purpose.

Whatever its location might be found to be, if possible to find it, it would not in any way affect the character of the work to be done, the treatment of the pier would remain the same. Furthermore, as you must be aware, Pier 4 is surrounded with rip-rap, and in sinking our caissons around that pier we went through a solid mass of rip-rap stone nearly all the way down; consequently, it will be practically impossible to get a rod or a hook down the side of the old crib, so as to reach the cutting edge of the old caisson underneath it. This I believe was finally accomplished with some uncertainty at Pier 2, but in my judgment it will be entirely impossible at Pier 4, and it will be very foolish, after the coffer-dam is pumped out and we are ready to concrete, to waste any time or assume any risk in any such idle experiments. You may safely take it for granted, that wherever the cutting edge of that old pier is, the pier is settling and leaning dangerously, and must have the support which we propose putting in there, and that just as quickly as possible when the water is pumped out.

"Answering your question directly as to hunting for this cutting edge, will say that, of course, if your company will assume all responsibility and all costs, direct and indirect, and all consequent damages, which might occur from floods and other disasters, by delaying the putting in of that concrete around Pier 4, after we are ready for it, then, of course, we will hunt for the cutting edge of that caisson, at your expense, just as long as you want to continue such investigations, but when you think the matter over carefully, I think you will agree with me that no time should be lost, after we are ready to concrete, for the purpose of satisfying curiosity. I am thoroughly satisfied myself as to where the cutting edge is under that old pier, and when you see the top of the old crib, you can satisfy yourself beyond a doubt as to where the bottom is.

"Very truly yours,

"A. J. TULLOCK,
"Proprietor."

APPENDIX D

LETTERS OF RALPH MODJESKI CONTAINING RECOMMENDATIONS FOR REINFORCEMENT OF THE PIERS.

"CHICAGO, ILL., August 5, 1911.

"MR. E. J. PEARSON,
"*First Vice-President,*
"Missouri Pacific Railway Company,
"St. Louis, Missouri.

"DEAR MR. PEARSON:—As had been prearranged, I visited, last Thursday, in company with Mr. C. E. Smith, Bridge Engineer, your two bridges at Little Rock, Arkansas. Most of the time was devoted to the examination of your Little Rock Junction Bridge, which is in a precarious condition. I have also carefully examined the plans and records of the old structure, together with what has been done to repair it.

"It would seem that the coffer-dams which were placed by pneumatic process around Piers II and IV did not get at the seat of the trouble, and as shown by Pier IV did not correct it. The original caissons were sunk to rock and the air chamber filled with concrete, but the cribwork above was filled with sand and possibly some rip-rap. There is no doubt in my mind that the concrete in the caisson chamber rests on rock. It would be difficult to suppose that the engineers had come within a foot or two from rock and had failed to remove that thickness of material before sealing the chamber. The records as well as the tradition seem to indicate positively that the air chambers were sealed with concrete. There seems to be no doubt therefore that the trouble occurs in the cribwork above, which, instead of being filled with concrete as it should have been, was filled with sand and possibly some rip-rap. This sand is probably leaking out through the openings in the outside sheeting and is settling away from the timbers, so that the entire load is carried on those timbers, which under a load of something like four or five hundred pounds per square inch are crushing.

"I should like to have one or two more days to consider this whole matter carefully, and will therefore not make this my final report as to what is best to be done. I have no doubt, however, that what we should attempt to do is to remove the sand from the inside of the cribs and replace it with concrete. If that is done to all the piers it would afford excellent foundations for future piers which you may wish to construct for a new bridge or else it would support the present piers as long as the piers themselves held together.

"Pier III is the one which should receive immediate attention as it is gradually settling at a rate which in a few months time

would mean its total destruction. In conference with Mr. Smith it was agreed that a plant be rigged up on a barge for taking wash-borings around the pier to find out if there is sufficient rip-rap present to prevent driving a wooden triple-lap sheet-piling coffer-dam. It is also desirable to arrange as soon as possible to bore at least two holes in the up-stream corners of the coffer-dam to find just how much material is left inside of it, and also incidentally to find whether the working chamber has actually been sealed with concrete.

"My present plan would be to drive a coffer-dam around the pier at a distance of say 6 ft., from the walls of the old crib and to pump it out, lowering the water level sufficiently to examine the old crib by partly removing the outside planking. While this is being done it would be quite advisable to partly support the up-stream end of Pier 3 by shores which in their turn would rest on piles driven alongside the old coffer-dam. Mr. Smith is familiar with what I have in mind.

"Whatever work is done, it will have to be performed carefully and step by step, in order not to endanger the present pier. It is not possible to foresee all the difficulties that may be encountered, but I am quite confident that the work can be done at a reasonable cost.

"I would recommend that the work be done by Company forces, thus saving considerable time and possibly expense as well.

"I expect to write you again Monday, after studying the situation a little further.

"Very truly yours,

"RALPH MODJESKI."

"CHICAGO, August 7th, 1911.

"MR. C. E. SMITH,
"*Bridge Engineer,*
"Missouri Pacific Railway,
"St. Louis, Mo.

"DEAR MR. SMITH.—I have been thinking a great deal about the Little Rock proposition since I saw you at St. Louis, and I cannot arrive at any more satisfactory solution than the one which I outlined. There is another possibility, however, which occurred to me, and that is that it may not be necessary to drive a coffer-dam around the pier at 6 ft. distance from the old coffer-dam. The farther away we go the more difficult it would be to keep the water out during pumping. I would suggest, therefore, that, as contemplated, you take the soundings and borings to ascertain how much rip-rap there is around the pier, and then either simultaneously or immediately thereafter arrange to bore a hole through the corners of the cribs vertically to find out how much sand or rip-rap or other material there is in the crib. It may be that if the material contained in these

cribs is merely sand or such material as can be pumped out, it will be sufficient to drive a Wakefield sheet-pile coffer-dam at a distance of 1 ft., for instance, in which case it would be very easy to excavate the material between the old crib and the coffer-dam and seal the bottom with concrete. It would take very little concrete and of little thickness to hold water. After this is done we could pump out the coffer-dam sufficiently to get at the top timbers of the crib. We could then remove these timbers at least partly and remove as much as possible of the material inside. It is probable that we might be able to pump out the water from the interior of the crib and then fill it with concrete in the dry.

"Very truly yours,

"RALPH MODJESKI."

"CHICAGO, August 19, 1911.

"MR. E. J. PEARSON,

"Vice-President, Missouri Pacific Railway,

"St. Louis, Mo.

"DEAR MR. PEARSON: Since writing you the report on the Little Rock Junction Bridge, I have been thinking the matter over, and it occurs to me that if the Company desires to maintain this bridge for some years to come and perhaps build a new superstructure on it, it would be cheaper in the end to rebuild the piers of concrete, at least Piers 3 and 4, which are causing the most trouble. Pier 3 is in a precarious condition, and no method of repairing, unless it be a very expensive one, can be counted on with absolute certainty to produce satisfactory results, and at best the masonry in the present piers is not in the very best condition, many of the stones being cracked, and while it may last for many years, it would have to be replaced some time or other. I would respectfully suggest that you authorize the reconstruction of Piers 3 and 4 at this time. In this way the masonry can be taken down and the cribs filled solid with concrete at much less expense than could be done with the piers in place. The concrete piers could be built for a reasonable amount and part of that cost would be offset by the saving in the cost of the foundation repairs, which repairs, as stated, would be rendered considerably easier.

"Kindly advise me what your wishes are in this respect.

"Very truly yours,

"RALPH MODJESKI."

APPENDIX E

List of Equipment Used in Repairs to Pier 3.

1 barge, 24 by 80 ft. with derrick.
1 barge, 18 by 60 ft.
1 barge, 16 by 50 ft.
1 barge, 15 by 24 ft.
1 rowboat.
1 compressor, 18 by 18¼ by 24 in., with receiver and mains.
2 air locks.
2 hoisting engines.
3 horizontal boilers.
1 derrick.
1 orange-peel dredge, ¾-yd.
1 pile leads and hammer (not used).
1 No. 4 Emerson pump.
1 pulsometer.
1 12 by 7 by 12 Fairbanks-Morse pump.
1 D. C. centrifugal pump, 8-in.
2 steam jets.
1 diaphragm pump.
1 double-drum crab.
1 No. 11 Smith mixer.
4 steel concrete cars.
1 turntable.
6 steel concrete buckets.
1 steel tremie.

PROOF OF AN ASSUMPTION IN THE THEORY OF CONCRETE BEAMS.*

By Ralph E. Goodwin, Jun. Am. Soc. C. E.

Synopsis.

The object of this paper is to present a mathematical justification of the theory that a section of a beam which is a plane before bending remains a plane after bending, as applied to beams of reinforced concrete.

The proof is based on the principle of least work.

The assumptions are those usual in the theory of reinforced concrete design, with the exception of that of a plane before and after bending, which is assumed to be true of the compression side of the beam, but not of the beam as a whole.

It is important to notice that the value of the conclusions depends on the accuracy of the assumptions. No assumptions are made in the proof, however, which are not commonly used in reinforced concrete design.

The common theory of reinforced concrete beam design is based on the assumption that a section which is a plane before bending remains a plane after bending. This assumption is borrowed from the common theory of flexure, and is so familiar to engineers, through its application to beams of homogeneous material, that the correctness of applying

* This paper will not be presented at any meeting of the Society, but written communications on the subject are invited for subsequent publication in *Proceedings*, and with the paper in *Transactions*.

it to beams of reinforced concrete is seldom questioned. Nevertheless, the difference between a beam of homogeneous material and a composite beam of concrete reinforced with steel is so great that an assumption which is reasonable in the case of the former is not necessarily reasonable in the case of the latter, and textbooks on the subject should furnish more plausible reasons for the theory of a plane before and after bending than they usually advance.

There follows a mathematical justification of the principle in question, which is based on the principle of least work. It is assumed that the correct value of j (arm of resisting couple) is the value which develops any given M (resisting moment) with the minimum of work expended in bending the beam. The method of proof used is to compute the value of j by the method of least work and to show that the value thus determined is the same as that in common use.

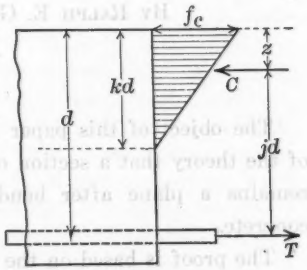

FIG. 1.

In the work which follows, the assumptions usual to the theory of reinforced concrete design are made, with the exception of that of a plane before and after bending, which is assumed to be true of the compression side of the beam, but not of the beam as a whole (Fig. 1).

The symbols used are the standard notation. In addition,

dl = the distance between two adjacent cross-sections of the beam before bending.

W_{dl} = the work done in straining a section of the beam of length, dl.

W_{dl} = (work of straining steel on tension side) plus (work of straining concrete on compression side).

According to the principles of mechanics, the work done by a load gradually applied is one-half the force multiplied by the distance.

Hence,

$$W_{dl} = \frac{1}{2} C \frac{2}{3} \frac{f_c}{E_c} \times dl + \frac{1}{2} T \frac{f_s}{E_s} \times dl$$

$$= \frac{1}{2} \left(\frac{f_c b k d}{2} \right) \frac{2}{3} \frac{f_c}{E_c} \times dl + \frac{1}{2} (A f_s) \frac{f_s}{E_s} \times dl$$

$$W_{dl} = \frac{f_c^2\, b\, k\, d}{6\, E_c} \times dl + \frac{f_s^2\, A}{2\, E_s} \times dl \qquad (1)$$

$$M = \frac{f_c\, b\, k\, d}{2} \times j\, d = f_s\, A\, j\, d\,;$$

$$f_c = \frac{2\, M}{b\, k\, j\, d^2} = \frac{2\, M}{3\, b\, (1-j)\, j\, d^2}; \quad f_s = \frac{M}{A\, j\, d}.$$

Substitute these values in Equation (1).

$$W_{dl} = \left(\frac{2\, M}{3\, b\, (1-j)\, j\, d^2}\right)^2 \frac{3\, b\, (1-j)\, d}{6\, E_c} \times dl + \frac{M^2}{2\, A\, j^2\, d^2\, E_s} \times dl$$

$$= \frac{M^2}{2\, d^3\, b\, E_c} \left\{ \frac{4}{9\,(1-j)\, j^2} + \frac{1}{p\, n\, j^2} \right\} dl$$

$$= \frac{M^2}{2\, d^3\, b\, E_c} \left\{ \frac{4\,(j^2 - j^3)^{-1}}{9} + \frac{j^{-2}}{p\, n} \right\} dl.$$

To find the value of j which will make W_{dl} a minimum, set the first derivative with respect to j equal to zero.

$$\frac{d\,(W_{dl})}{d\,j} = 0 = \frac{M^2}{2\, d^3\, b\, E_c} \left\{ \frac{-4\,(j^2 - j^3)^{-2}\,(2\,j - 3\,j^2)}{9} - \frac{2\, j^{-3}}{p\, n} \right\} dl;$$

$$0 = \frac{4\,(2\,j - 3\,j^2)}{9\,(j^2 - j^3)^2} + \frac{2}{p\, n\, j^3};$$

$$0 = \frac{1}{j^3\,(1-j)^2} \{ 4\, p\, n - 6\, j\, p\, n + 9\,(1-j)^2 \}.$$

Each factor, when set equal to zero, gives a root of the equation. The root desired lies in the last factor,

$$0 = 4\, p\, n - 6\, j\, p\, n + 9\,(1-j)^2;$$

$$0 = j^2 - \frac{2}{3}\, j\,(p\, n + 3) + \left(1 + \frac{4}{9}\, p\, n\right).$$

Solving for j by completing the square in the above equation gives,

$$j = 1 - \frac{1}{3}\left(\sqrt{2\, p\, n + (p\, n)^2} - p\, n\right) = 1 - \frac{1}{3}\, k.$$

Hence $$k = \sqrt{2\, p\, n + (p\, n)^2} - p\, n.$$

This is the value of k in common use. *Q. E. D.*

For beams reinforced for compression and for T-beams the demonstration is similar to the foregoing, up to and including the placing

of the first derivative equal to zero. From that point the general solution becomes so complicated that it is best to continue as follows,

(1) Assume numerical values for p, p', d, d', n;

(2) Compute the numerical value of k from the formula in common use;

(3) Substitute the foregoing values in the following equation:

First derivative of work with respect to $k = 0$.

It will be found that the equation in (3) is always satisfied by the values assumed in (1) and (2). *Q. E. D.*

DEPRECIATION AS AN ELEMENT FOR CONSIDERATION IN THE APPRAISAL OF PUBLIC SERVICE PROPERTIES.*

By C. E. Grunsky, M. Am. Soc. C. E.

Synopsis.

The object of this paper is to bring nearer to standardization the methods of dealing with depreciation when valuations are made for rate-fixing purposes; to show that the repayment to the owner of invested capital has nothing to do with depreciation; to show that the investment should not be returned to the owner unless he is to be bought out; to show that a public utility taken as a whole may be regarded as having unlimited life; to show that in fixing rates the replacement requirement may with advantage be allowed to take the place of the depreciation allowance; to show that departure of actual from probable life should be taken into account in estimating replacement requirements or depreciation; and to show that the method here called the Unlimited-Life Method of making appraisals is better suited than other methods, to serve as the basis for estimating necessary earnings.

* This paper will not be presented at any meeting of the Society, but written communications on the subject are invited for subsequent publication in *Proceedings*, and with the paper in *Transactions*.

All methods of valuing public service properties for rate-fixing purposes—to be fair to both owner and rate-payer—should be in continuous application from the beginning of operation.

It follows from this that the past history of expenditures and earnings should be given consideration and that it may be unfair to assume that, because of depreciation in fact, a part of the investment has been amortized and that if not amortized the fault is the owner's. (Knoxville case.)

The invested capital should remain unimpaired. The owner's earnings should include whatever may be necessary to meet maintenance, repairs, and replacements, but no part of his investment should be returned to him, unless the acquisition of the property is involved.

The situation is not altered even in those cases in which the owner diverts to outside uses the funds which he has earned to meet replacements. The owner's obligation to replace the worn-out parts remains, and must be met if the rate-payer is to be served satisfactorily.

Amortization of the invested capital becomes necessary only when the public service property is to be acquired by the public.

The allowance in the earnings which is usually made to the owner under the name of depreciation, whether applied to this use or not, is really intended as an allowance to meet replacements.

Replacement requirements can be determined from the cost to replace and the time when the replacement will probably take place.

The time when an article which has already been in use for some time—which, in other words, has acquired age—will go out of service cannot be determined by subtracting the age from the probable life of a new similar article. It is dependent on the condition of the article. It is approximated from the article's expectancy—from its remaining probable life. Expectancy changes with age.

When expectancy is given due weight, the application of the Equal-Annual-Payment and other similar methods of valuation becomes difficult if not impracticable.

Expectancy is capable of much closer approximation than by the subtraction of age from probable life.

Taken as a whole, each public service property may be regarded as having unlimited life. The probable life of its parts—whether only a railroad tie or an electric generator—does not alter this unlimited life

of the whole. The expectancy of each part, however, may be used in estimating the "owner's obligation to replace," which is another name for what is usually called "accrued depreciation".

The obligation to replace each part, expressed in dollars, grows with the age of the part. If the replacement requirement is properly estimated and covered by the earnings, the owner can keep the plant at 100% efficiency, based on the standard established by the plant itself; but such replacement allowance cannot be regarded as a return of capital until the time comes when the owner is relieved of any further obligation to replace.

The rate of depreciation is an aid in making an advance determination of the replacement requirements, and to this extent is an element to be considered in fixing rates.

The accrued depreciation, or the accrued obligation to replace discarded or inefficient articles, becomes of interest when for any reason the remaining value of physical elements is to be ascertained.

Conclusion.—The Courts are in error when they hold it to be always necessary to give depreciated value consideration when rates are to be fixed.

The fair application of any method of valuation to a property which has acquired age, when this valuation is to be used as a basis for fixing service rates, involves due consideration of past history, particularly in so far as the method is concerned by which necessary earnings in the past were estimated.

Continuity of application is essential to the fairness of the various methods of making appraisals for rate-fixing purposes.

No part of the capital properly invested in a public service property should be returned to the owner until a transfer of ownership to the public is contemplated.

The appraiser should concern himself with the replacement requirements, rather than with amortization of capital or with depreciation.

In estimating depreciation, accrued depreciation, or replacement requirements, the expectancy, properly determined, should be substituted for probable life new less age.

All public service properties should be regarded as having an unlimited life, and, if thus regarded, a new method of valuation becomes possible in which operating expenses are made to include the

replacement requirements and under which there will be no amortization of capital.

The Unlimited-Life Method of valuing public service properties has the great advantage of requiring the smallest earnings in the early years of the property's life; it is simpler than all others in its application; and it is fair to both owner and rate-payer.

Despite the tendency which is apparent on the part of the Courts and the public service commissions, and especially on the part of the lawyers and experts who represent the rate-payers, to favor appraisals based on cost of reproduction, less depreciation, as a vital element to be considered in fixing rates, there is no doubt that there will be a backward swing of the pendulum, and that the fundamental principle will ultimately be recognized, under which the owner of a public service property will be regarded substantially as the agent of the rate-payer; and, as such, will be allowed, and may even be required, to keep his investment in the property unimpaired and undiminished, just as would be the case if the rate-payers themselves, through the agency of a municipality or otherwise, had constructed the public service plant. This is good policy, sound in every way, and, when well understood, being absolutely fair to all concerned, providing as it does for the most reasonable apportionment of earnings to various periods of a plant's life, should, in all cases in which it is applicable, prove acceptable alike to the rate-payer and to the owner.

Some of the public service commissions of the country, as well as the Courts, are confounding "amortization" with "depreciation". The result is unfortunate, and has led valuation experts to adopt all sorts of subterfuges to secure for their clients that equity to which, whether rate-payers or owners, they are entitled.

It has become common practice, nevertheless, frequently an improper practice, to regard as a repayment of capital all so-called "depreciation" which has been allowed in the earnings (and, let it be assumed, which has actually been collected from the rate-payer).

Any repayment of capital is "amortization", and has nothing whatever to do with the depreciating service value of any part of a public service plant.

The repayment of capital (amortization), which it has become customary to assume is taking place when earnings include an allow-

ance for depreciation, is an unfair burden on the rate-payer in the early years of operation.

This can be and is avoided under the rational system of making suitable provision for the replacement of worn-out parts of the property, instead of endeavoring to amortize the investment.

To make this clear and to point out some of the errors into which Courts and some experts are drifting is the main purpose of this paper. Incidentally, a fact which is too often lost sight of will be emphasized, namely, that the various methods of computing the current depreciation allowance which should be covered by the earnings are only then correct when applied consistently and continuously throughout the probable, or, as the case may be, the useful, life of an article; that, therefore, the dictum of the Courts, according to which no regard should be paid to the fact that past earnings may have been insufficient to provide a depreciation fund, is at fault, and should be suitably modified or at least qualified.

The writer will endeavor, moreover, to show that appraisals for rate-fixing purposes may always be made at the full amount of the investment and that, when applicable, the method of computing and allowing replacement requirements under the assumption that the property as a whole has unlimited life, instead of allowing depreciation as ordinarily defined, is the one which should find general acceptance.

Fair Value.—The term "fair value" as used in connection with rate-fixing is difficult to define. This term is used in a measure, no doubt, for the purpose of ruling out "book value" or actual investment, which may include items and amounts of doubtful propriety, and to rule out values based on stock and bond issues and the market values of such securities. The term has not yet been defined satisfactorily, and no attempt will be made here to reconcile divergent views in relation thereto; but attention may be called to the difficulty which has been experienced by all who have attempted to make appraisals for rate-fixing purposes, in reconciling "fair value" to a purchaser with the "fair value" which is to be considered when fixing rates. Why should there be one valuation for purchase and another for rate-fixing? The answer that has been given by the Courts (Knoxville case) is practically to the effect that there should be no such difference, and experts have been put to it to determine values so that any such difference shall disappear.

The value to an investor is unhesitatingly determined from the net earnings, with due regard to hazards of the business. The value for rate-fixing purposes is to be that value on which, with the same regard for the hazards of the business, the owner is to be allowed to earn a fair interest return. Value should be the same whether determined by a rate-fixing body or whether determined for a purchaser. "Fair Value", then, is necessarily based on proper and reasonable investment which may be ascertained from cost records, and when cost records are not available, is usually estimated by the "cost-of-reproduction" method. Any determination of value by comparison with the cost of the next best substitute for the established utility is at times unwarranted and absurd, and has no place in determining the equities between the owner and the public whom he is serving, beyond establishing an upper limit of possible value.

"Fair Value" may include certain more or less indeterminate elements, such as the cost of establishing the business, including early deficient earnings; but no definite or precise rules can be laid down for determining these, as it would be eminently unfair to reward the least successful enterprise which shows greatest early losses and highest unproductive expenditures, by granting it the greatest allowance for so-called "going concern" or "establishment of business" or other similar values.

"Investment" or "Capital Invested."—This is the aggregate of the reasonable and proper expenditures which have been made to render the property in question efficient for the purpose for which it is intended.

"Depreciation."—This is the lessening in worth of any perishable article or property. It is not, therefore, to be measured by inherent deterioration, due to wear and tear, but solely by a comparison between the probable life, the expectancy, and the cost of replacement at the expiration of the term of the article's actual serviceability.

"Annual Depreciation" or the "Annual Depreciation Increment."—This is the annual theoretical lessening in worth, expressed in dollars.

"Accrued Depreciation."—This is the difference between the original cost and the "remaining value".

"Remaining Value" or "Present Value."—This is the present worth of any article, dependent on, and to be computed from, the three elements: (*a*) the probable useful life of the article new; (*b*) its probable remaining life; and (*c*) the cost of replacement, which, when prices

are not subject to change, is the original cost less the residual value of the article when it goes out of use.

"Residual Value."—This is the value which remains in any article after it has ceased to be useful as an integral part of the public service property. It may be scrap value, or it may be the price at which it is disposed of for use in connection with some other property. It is usually estimated as the value to an outside purchaser, less the cost of delivery to such purchaser.

"Unrecovered Depreciation" or "Uncollected Replacement Annuities."—This refers to the allowed depreciation increment or to the allowed replacement annuity which the earnings are inadequate to cover, and which, in consequence thereof, could not be collected.

"Probable Life."—This is the probable time, usually expressed in full years, during which any article will render efficient service. This is to be determined from the sum of experiences with like articles and with due regard to local conditions. It depends not alone on the time required for an article to deteriorate and become valueless by use, by ordinary wear and tear, but also on the time when, by reason of accidental destruction, inadequacy, or obsolescence, the article must be replaced by a new one better adapted to fulfill its purpose.

"Remaining Life" or "Expectancy."—This is the probable time, expressed in years, during which any article which is no longer new will continue to render efficient service. The remaining life cannot always be determined from the probable life of the article when new by subtracting therefrom its age. The condition of the article and the local circumstances should be taken into account in estimating the remaining life.

A high-duty pump, which originally had a probable life of 25 years, when it reaches the end of this term, may be in a condition almost as good as new. It has escaped the possible accidents of the early years of its life, and by careful attention and replacements of its wearing parts is still rendering first-class service. The value of this pump is not to be written off the books, neither should it be regarded as good as new. Its value is ascertained by determining its probable additional years of usefulness and the probable cost of replacing it at the end of the new term.

An irrigation canal usually improves with age. So far as wear and tear is concerned, it has unlimited life; but, under the develop-

ment of extensive areas, the small original canal may in the course of time be superseded. The probable life of this canal, and therefore, too, the annual replacement increment, is estimated on some assumption relating to the rate of this development. Finally the time comes when the project for a comprehensive canal system has taken definite shape and it may reasonably be assumed that within a definite period, five or ten, or some other number of years, the original canal will be superseded; its diverting dam and its head-works, and perhaps the canal itself, will then be abandoned. The remaining life or expectancy of the canal is at that time only five or ten, or some other number of years, as the case may be, and within this time the remaining investment in or the value of the canal is the amount under consideration for replacement.

"Amortization."—In the sense in which this term is used in this paper, it applies to the retirement of capital. Ordinarily, the discarded article is replaced by a new one which will render equivalent or better service. The capital to be amortized during the life of the article is, for all practical purposes, its replacement cost, being the cost of installing an equivalent new article, less the residual value of the original article.

"Annual Replacement Increment" or "Replacement Annuity."—These are terms used to designate an annual allowance or an annual contribution to a replacement fund, such that this annual allowance, together with interest thereon (at the rate of the net earnings of the property) will, during the life of any perishable article, amount to its replacement cost.

"The Obligation to Replace."—This is an obligation, carried by every owner of public service property, to replace articles forming essential parts of public service plants when worn out or no longer capable of rendering adequate service. The "Obligation to Replace", when expressed in dollars, is equivalent to the accrued theoretical depreciation or to the sum which should have been earned and accumulated to meet necessary replacements. This obligation to replace, together with deferred maintenance, must always be considered by the appraiser of property which is to be purchased. The investment less this obligation to replace (also less deferred maintenance) is, in other words, a measure of present worth.

"Deferred Maintenance."—This is the neglect, expressed in dollars, which has resulted from failure to keep an article in good condition and repair. It is the sum which should at once be expended to restore the article to ordinary good service condition, and to protect it in such a way against causes of rapid destruction that its deterioration will not be unduly rapid. Ordinarily, there should be no "deferred maintenance." By proper attention to maintenance and repairs, the service rendered should be up to the standard which is expected of the plant. In other words, the plant should, practically at all times, be at 100% efficiency.

"Wear and Tear."—This is the term applied to the deterioration of an article from use. The article is kept in serviceable condition by the renewal of its worn-out parts and by suitable attention to its wearing parts. Maintenance and repair are to be included in operating expenses, and are not covered by depreciation in the sense in which used in this paper. The expenditures for repairs and maintenance are intended to keep the article at or near 100% efficiency. Repair and maintenance expenses usually increase somewhat with the age of an article, and, when this increase is worthy of note, may be an element to be taken into account in determining present worth.

"Replacement Cost."—This is the cost of the article with which a worn-out article is replaced, less the residual value of the original article. It is the cost of effecting a change from the worn-out part to a new part of equal service value. This is sometimes called "wearing value."

"The Sinking-Fund Method."—This method of making appraisals and of determining necessary earnings is one under which the annual allowance for depreciation is uniform in amount. This depreciation allowance is the annuity which, together with interest at the rate of the net earnings of the property, will, during the probable life of an article, amount to its replacement cost. The replacement, it is assumed, is to be accomplished at the end of the probable life of that article. There is no repayment of capital. The investment remains undiminished. This, therefore, is a 100% valuation method and might be thus designated. It is the method referred to by the writer as Method No. 1, in a former paper* on appraisals.

* "The Appraisal of Public Service Properties as a Basis for the Regulation of Rates," *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 828.

The "Equal-Annual-Payment Method", as described in the report of the Special Committee on Valuation, as presented to the Annual Meeting of January 21st, 1914, refers to that method which makes the annual depreciation, or amortization increment, an amount increasing from year to year. The annual depreciation is estimated by sinking-fund methods. It is, for any year, equal to the annuity which will retire the remaining value in the remnant of the original probable life term and, uniformity of interest rates being assumed, it will, when added to the interest on the remaining value, always amount to the same sum. The application of this method is exactly equivalent to the application of the Sinking-Fund Method.* When depreciation allowances computed under this method are actually earned from the time an article goes into service, they may be considered as refunds of invested capital. The invested capital, in that case, decreases as depreciation; if thus earned, it accrues. Depreciation earnings may properly be regarded as being thus applied to retired capital, but this method of estimating what should thus be earned from year to year is undesirable, because it involves frequent, elaborate, and cumbersome re-estimates of remaining value, requiring the services of experts, although it is absolutely identical in results with other methods which have the advantage of simplicity. Furthermore, when not applied from the beginning, there may never be any surplus in such an amortization account for application to a refund of early investments and this portion of the investment may remain undiminished.

"The Straight-Line Method."—This "method of estimating the annual depreciation", or "the annual amortization installment", makes the annual amortization of capital uniform throughout the probable life of an article. The annual amortization installment is estimated from the original cost of an article and its probable life, by dividing the cost by the number of years. This, like any other amortization method, is justified on the theory of the immediate application of an annual installment to the retirement of capital. In this respect there is an essential difference between this and the Sinking-Fund Method, under which no capital is retired, and also between this and the Unlimited-Life Method, under which, also, there is no retirement whatever of the investment.

* *Transactions*, Am. Soc. C. E., Vol. LXXV, pp. 827–829–834–842, etc.

"The Unlimited-Life Method."—This method of making appraisals which are to serve as a basis for fixing rates, has been referred to in the writer's paper on appraisals.* In that paper the term "perpetual life" was used. It is believed to be more appropriate to use the designation here suggested.

Nearly all public service properties, taken in their entirety, may be regarded as having unlimited life. There is then no accrued depreciation to be deducted in making the appraisal. The property is kept in good condition by the repair of its parts and by replacements as these parts become useless and have to be discarded. No part of the investment is returned to the owner, but, as the plant grows old and one part after another has to be replaced, he must be allowed to recover in the earnings the cost of each article as replaced. It is on this principle that many complex, and particularly public service, properties are operated. In the early years of the life of a property made up of many parts, such as rails and ties, the replacement requirements will be small. As the property acquires age, the replacements —provided that extensions are relatively unimportant and negligible in comparison with the extent of the property under consideration— will gradually increase to nearly the amount indicated as amortization by the Straight-Line Method. The departure from this amount will be dependent on the annual extensions of the system in relation to the entire investment. There will be ultimate agreement between the replacement requirement and the straight-line amortization increment, if the plant is one that has ceased to grow. The valuation for rate-fixing purposes will always be at 100%, and the replacement requirements, until definitely ascertained by experience, will be approximated with due consideration of the age and the probable life new of the individual parts of which the property is made up.

Diagrammatic Illustrations.

The foregoing definitions, relating to depreciation, to replacement annuities, to the obligation to replace, and to amortization, can best be made clear by reference to diagrams Figs. 1 to 5.

These diagrams, being for the purposes of illustration, apply to the special case in which the article under consideration has no residual or scrap value at the time of its replacement, and in which the new

* *Transactions*, Am. Soc. C. E., Vol. LXXV, pp. 805, 815, and 875.

article which replaces it costs the same as the original article and has the same service value.

Referring to Fig. 1, illustrating the Straight-Line Method: $A\ B$ is the original investment of capital in an article, subject to depreciation. $I\ J$ is the portion of the original investment which has been amortized (sometimes regarded as the accrued depreciation). $K\ L$ is the annual amortization increment. $H\ I$ is the remaining investment. $A'\ B' = A\ B$ is the replacement cost. $B\ A'\ B'\ A''\ B''$, etc., is the investment line showing for any particular time the amount of capital still invested in the article under consideration. $M\ N$, in the earnings diagram of Fig. 1, represents the interest on the remaining value. $N\ O = K\ L$ represents the annual amortization.

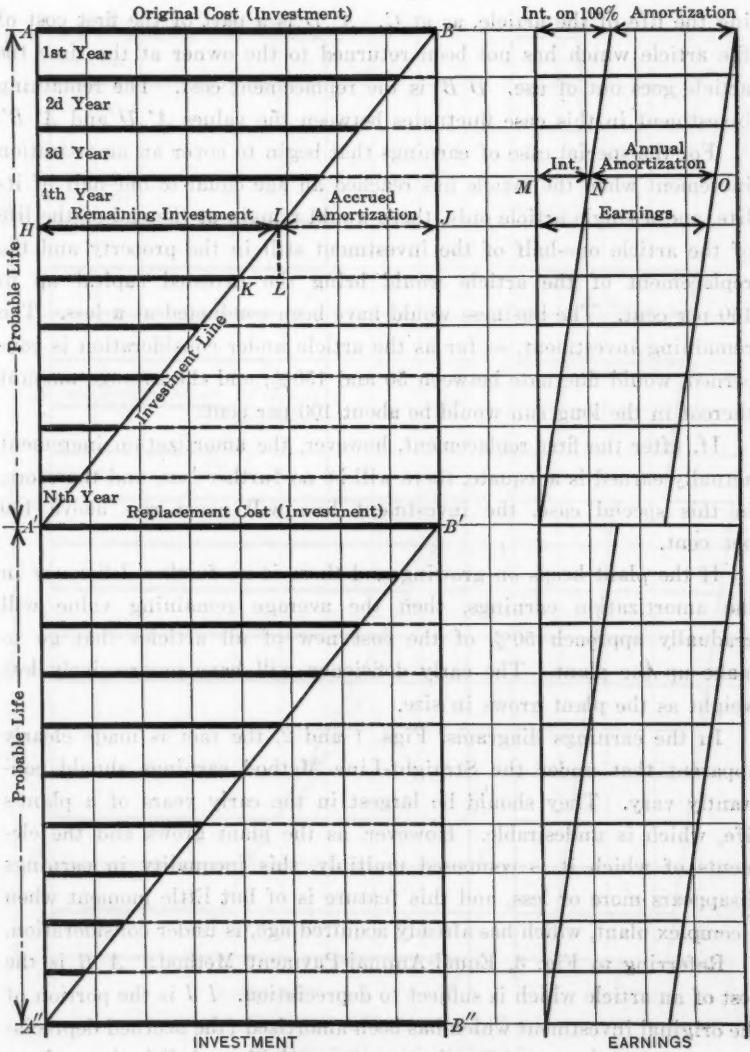
The owner is entitled to a reasonable return on the remaining investment, also to the straight-line amortization increment $K\ L = N\ O$, besides, of course, operating expenses, including taxes, insurance, etc.

The fluctuations in the amount of capital remaining in the property are shown by the "investment line." They range from 100% for the article new to nothing at the end of its term of life. The capital returned to the owner, whether under the name of "capital amortization" or under the name of "depreciation", is his, to do with as he pleases. It is immaterial whether he places it in a special depreciation fund; whether he makes outside investments therewith; or whether, as the property develops, he reinvests it in the extensions thereof, provided, of course, that at the end of the life of the article he is prepared to reinvest the capital required to replace it. If correctly estimated and earned from the beginning, the accumulation in the fund (without interest thereon, because such interest must be regarded as outside earnings) will be just adequate to replace the worn-out article.

Under this method of amortizing capital, the earnings must be somewhat larger in the early years of the article's life than in the later ones. This is an objectionable feature.

For an infinite number of such articles, of all possible ages, the aggregate remaining investment will be 50% and the straight-line amortization increment will be just equal to the annual replacement requirement.

For a single article, in case the earning of the amortization increment does not begin until some years have elapsed, the investment line will take the shape of the broken line in Fig. 2.



STRAIGHT-LINE AMORTIZATION

FIG. 1.

Referring to Fig. 2, Incomplete Amortization Straight-Line Method: Amortization earnings are supposed to commence at some time during the life of the article, as at C. $A'\ D$ is a part of the first cost of the article which has not been returned to the owner at the time the article goes out of use. $D\ B'$ is the replacement cost. The remaining investment in this case fluctuates between the values $A'\ D$ and $A'\ B'$.

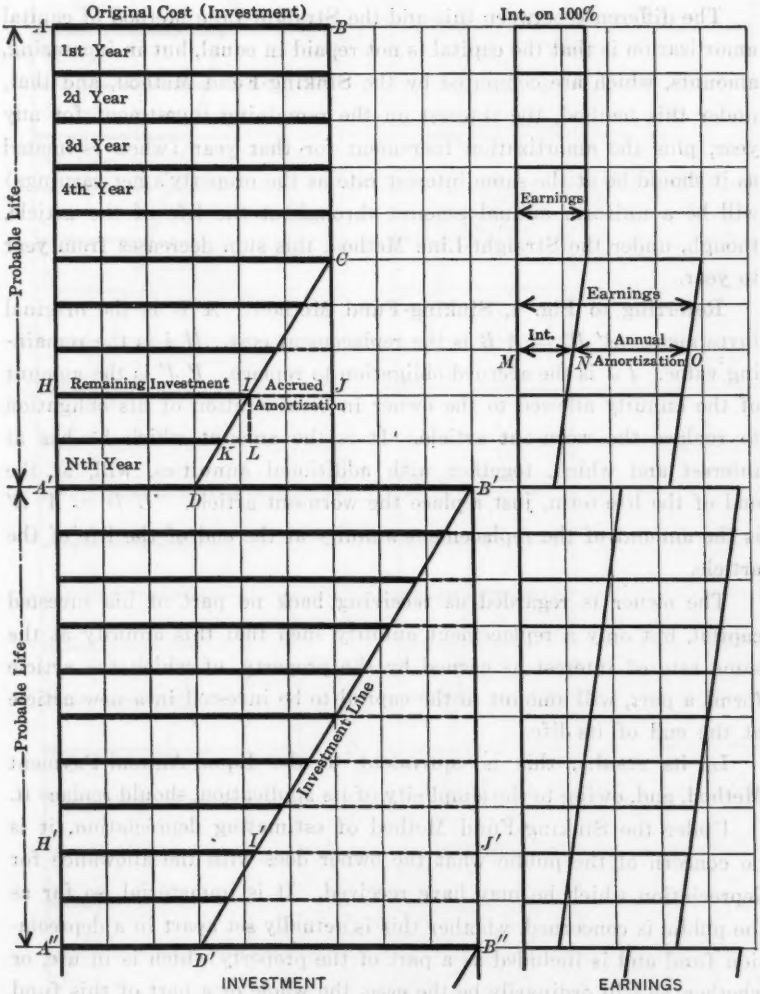
For the special case of earnings that begin to cover an amortization increment when the article has reached an age equal to one-half of its life, and a single article only, there would remain at the end of the life of the article one-half of the investment still in the property and the replacement of the article would bring the invested capital up to 150 per cent. The business would have been conducted at a loss. The remaining investment, so far as the article under consideration is concerned, would fluctuate between 50 and 150%, and the average amount thereof in the long run would be about 100 per cent.

If, after the first replacement, however, the amortization increment actually earned is adequate, there will be no further loss, and therefore, in this special case, the investment line will never rise above 150 per cent.

If the plant keeps on growing and there is no further deficiency in the amortization earnings, then the average remaining value will gradually approach 50% of the cost new of all articles that go to make up the plant. The early deficiency will have progressively less weight as the plant grows in size.

In the earnings diagrams, Figs. 1 and 2, the fact is made clearly apparent that under the Straight-Line Method earnings should constantly vary. They should be largest in the early years of a plant's life, which is undesirable. However, as the plant grows and the elements of which it is composed multiply, this inequality in earnings disappears more or less, and this feature is of but little moment when a complex plant, which has already acquired age, is under consideration.

Referring to Fig. 3, Equal-Annual-Payment Method: $A\ B$ is the cost of an article which is subject to depreciation. $I\ J$ is the portion of the original investment which has been amortized (the accrued depreciation). $H\ I$ is the remaining investment. $A'\ B' = A\ B$ is the replacement cost. $B\ A'\ B'\ A''$, etc., is the investment line representing for any particular time the amount of capital invested in the article under consideration. $M\ N$, in the earnings diagram of Fig. 3, represents the



INCOMPLETE AMORTIZATION
STRAIGHT-LINE METHOD.

FIG. 2.

interest on the remaining investment. $N\ O$ represents the annual amortization. $M\ N + N\ O$ is a constant.

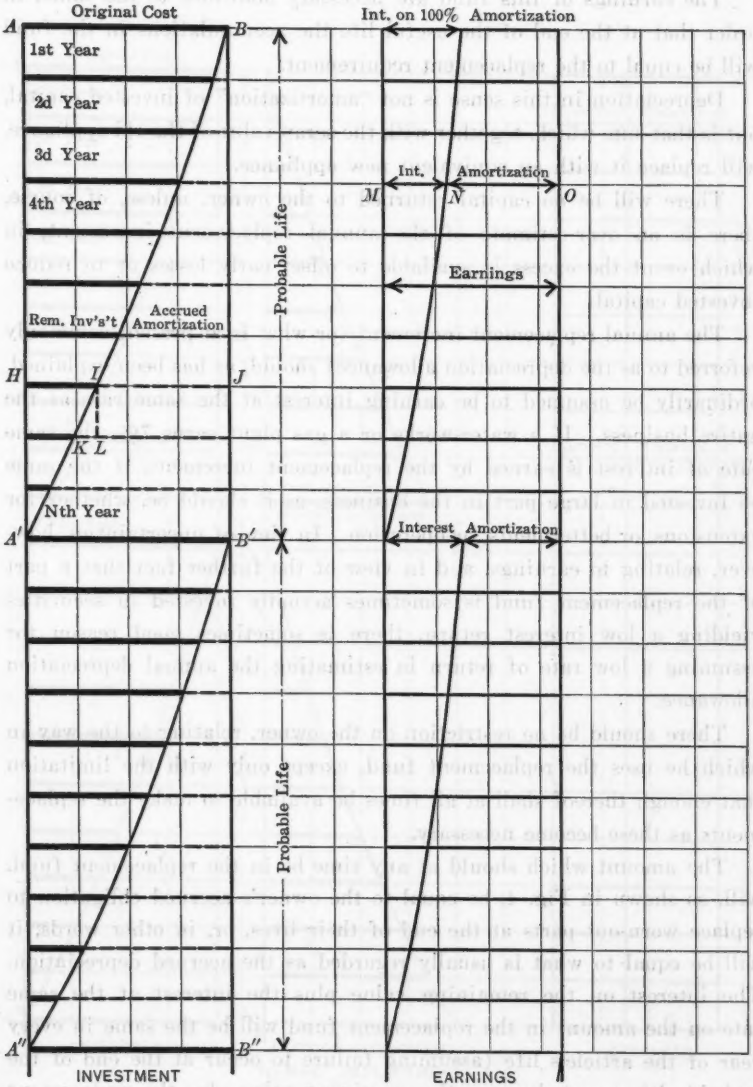
The difference between this and the Straight-Line Method of capital amortization is that the capital is not repaid in equal, but in increasing, amounts, which are computed by the Sinking-Fund Method, and that, under this method, the interest on the remaining investment for any year, plus the amortization increment for that year (when estimated as it should be at the same interest rate as the property's net earnings) will be a uniform annual amount throughout the life of the article, though, under the Straight-Line Method, this sum decreases from year to year.

Referring to Fig. 4, Sinking-Fund Method: $A\ B$ is the original investment. $A'\ B' = A\ B$ is the replacement cost. $H\ I$ is the remaining value. $I\ J$ is the accrued obligation to replace. $I'\ J'$ is the amount of the annuity allowed to the owner in consideration of his obligation to replace the worn-out article. It is the amount which he has at interest and which, together with additional annuities, will, at the end of the life term, just replace the worn-out article. $C\ D = A'\ B'$ is the amount of the replacement annuity at the end of the life of the article.

The owner is regarded as receiving back no part of his invested capital, but only a replacement annuity such that this annuity at the same rate of interest as earned by the property, of which the article forms a part, will amount to the capital to be invested in a new article at the end of its life.

In its results, this is equivalent to the Equal-Annual-Payment Method, and, owing to the simplicity of its application, should replace it.

Under the Sinking-Fund Method of estimating depreciation, it is no concern of the public what the owner does with the allowance for depreciation which he may have received. It is immaterial, so far as the public is concerned, whether this is actually set apart in a depreciation fund and is included as a part of the property which is in use, or whether, as will ordinarily be the case, the whole or a part of this fund is re-invested in extensions or betterments, or is entirely withdrawn from the business. The fact remains that this sum, real or imaginary, is an essential and integral part of the plant on which the owner is entitled to a return just the same as on the remaining value of the property.



EQUAL-ANNUAL-PAYMENT METHOD

(Amortization Computed by Sinking-Fund Methods)

FIG. 3.

The earnings of this fund are necessary additions to the same, in order that at the end of the useful life the accumulations in the fund will be equal to the replacement requirement.

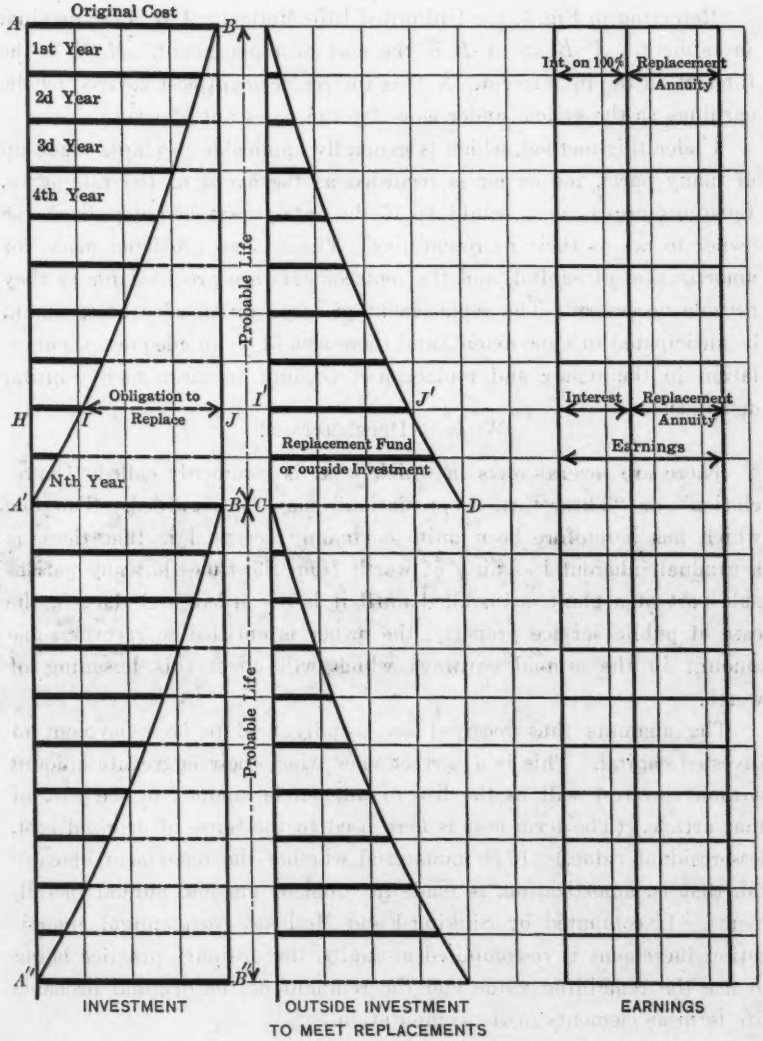
Depreciation in this sense is not "amortization" of invested capital, but is that sum which, together with the scrap value of the old appliance, will replace it with an equivalent new appliance.

There will be no capital returned to the owner, unless, of course, there is an over-estimate of the annual replacement increment, in which event the excess is available to offset early losses or to reduce invested capital.

The annual replacement increment (or what is at present commonly referred to as the depreciation allowance) should, as has been explained, ordinarily be assumed to be earning interest at the same rate as the entire business. If a water-works or a gas plant earns 7%, the same rate of interest is earned by the replacement increment, if the same be invested in large part in the business, as it should be, whether for extensions, or betterments, or operation. In view of uncertainties, however, relating to earnings, and in view of the further fact that a part of the replacement fund is sometimes actually invested in securities yielding a low interest return, there is sometimes good reason for assuming a low rate of return in estimating the annual depreciation allowance.

There should be no restriction on the owner, relating to the way in which he uses the replacement fund, except only with the limitation that enough thereof shall at all times be available to make the replacements as these become necessary.

The amount which should at any time be in the replacement fund. will, as shown in Fig. 4, be equal to the owner's accrued obligation to replace worn-out parts at the end of their lives, or, in other words, it will be equal to what is usually regarded as the accrued depreciation. The interest on the remaining value plus the interest at the same rate on the amount in the replacement fund will be the same in every year of the article's life (assuming failure to occur at the end of the probable life term), because the remaining value plus the replacement fund will at all times be 100% of the investment. The owner, therefore, as already stated, is entitled to earn a reasonable return on a 100% valuation (no deduction for depreciation) and also to earn an



SINKING-FUND METHOD

FIG. 4.

annuity which, together with interest thereon, will replace each article of which the plant is made up when it goes out of use.

Referring to Fig. 5, the Unlimited-Life Method: $A\ B$ is the original investment. $A'\ B' = A\ B$ is the cost of replacement. $M\ N$ is the interest on the investment. $N\ O$ is the replacement cost covered by the earnings as the article under consideration goes out of use.

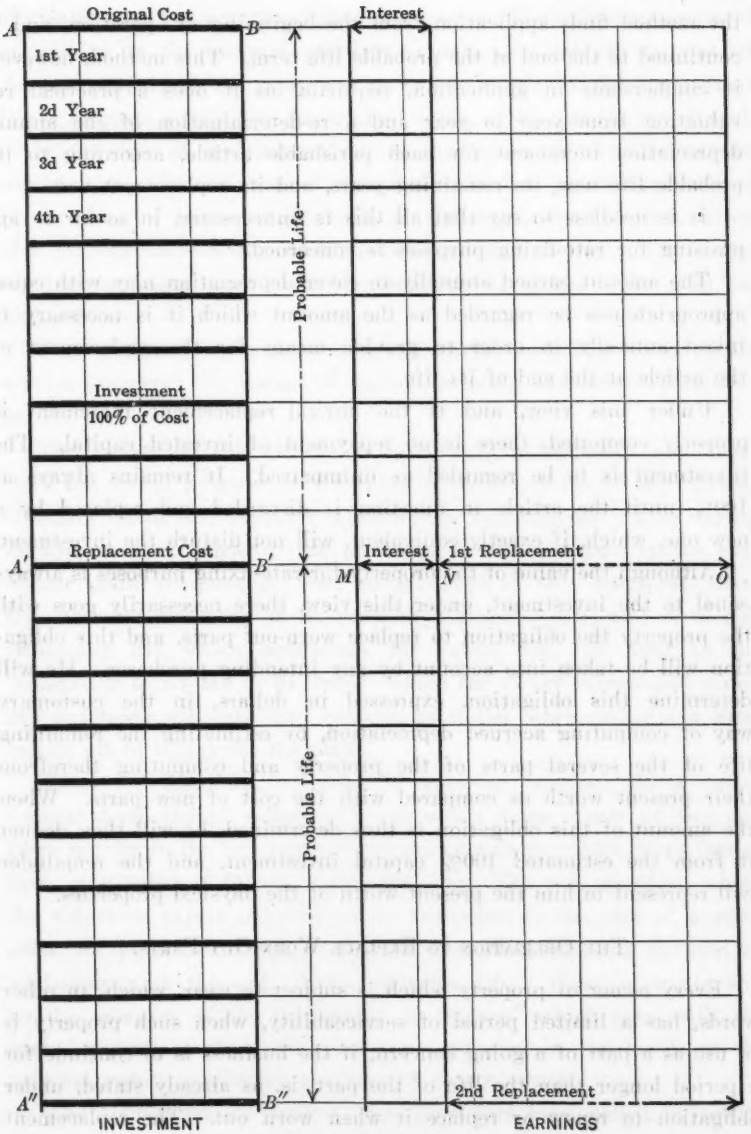
Under this method, which is generally applicable to plants made up of many parts, the owner is regarded as the agent of the rate-payer. Earnings are as they would be if the rate-payers had deputized the owner to act as their representative. There is no provision made for amortization of capital, and the replacements are provided for as they become necessary. The replacement of large units, of course, should be anticipated to some extent, and there should be an adequate accumulation in the repair and replacement account to meet such unusual demands.

What is Depreciation?

There are several ways in which what is commonly called "Depreciation" or "Theoretical Depreciation" may be regarded. The one which has heretofore been quite commonly accepted is that there is a gradual inherent lessening of worth from the time that any perishable part of a plant is installed until it is discarded, and that, in the case of public service property, the owner is entitled to recover some amount in the annual earnings which will offset this lessening of worth.

The amounts thus received are usually held to be repayment of invested capital. This is a correct view when their aggregate amount without interest will in the life of an article amount to the cost of that article. (The term cost is here used in the sense of original cost, less residual value.) It is immaterial whether the repayment of capital, that is, amortization, is made in equal or unequal annual installments. If computed by Sinking-Fund Methods, each annual amortization increment is re-computed annually, the ordinary practice being to use the remaining value and the remnant of the original probable life term as elements in the computation.

The repayment of capital in unequal annual amounts computed by sinking-fund methods is advocated by the Society's Special Committee on Valuation. This conforms to the layman's way of looking at the problem, and is sound in every particular, provided, of course, that



UNLIMITED-LIFE METHOD

(Extreme Case for a Single Article)

FIG. 5.

the method finds application from the beginning of operation, and is continued to the end of the probable life term. This method, however, is cumbersome in application, requiring as it does a practical revaluation from year to year and a re-determination of the annual depreciation increment for each perishable article, according to its probable life new, its remaining years, and its replacement cost.

It is needless to say that all this is unnecessary, in so far as appraising for rate-fixing purposes is concerned.

The amount earned annually to cover depreciation may with equal appropriateness be regarded as the amount which it is necessary to invest annually in order to provide means for the replacement of the article at the end of its life.

Under this view, and if the annual replacement increment is properly computed, there is no repayment of invested capital. The investment is to be regarded as unimpaired. It remains always at 100% until the article in question is discarded and replaced by a new one, which, if exactly equivalent, will not disturb the investment.

Although the value of the property for rate-fixing purposes is always equal to the investment, under this view, there necessarily goes with the property the obligation to replace worn-out parts, and this obligation will be taken into account by any intending purchaser. He will determine this obligation, expressed in dollars, in the customary way of computing accrued depreciation, by estimating the remaining life of the several parts of the property and computing therefrom their present worth as compared with the cost of new parts. When the amount of this obligation is thus determined, he will then deduct it from the estimated 100% capital investment, and the remainder will represent to him the present worth of the physical properties.

The Obligation to Replace Worn-Out Parts.

Every owner of property which is subject to wear, which, in other words, has a limited period of serviceability, when such property is in use as a part of a going concern, if the business is to continue for a period longer than the life of the part, is, as already stated, under obligation to renew or replace it when worn out. The replacement may be accomplished by the substitution of a new part exactly the same in all respects as the original one or the worn-out part may be replaced by apparatus of higher efficiency, of greater durability,

of greater cost, and perhaps of greater capacity. The obligation assumed in relation to the original property is only so much of the cost of the new apparatus or appliance as is equivalent to the investment in the original article, less its residual value, at the time it is replaced.

In the case of replacement due to inadequacy, this value may be considerable. In the case of destruction by fire, by violence, or as in the case of some article such as the small, wrought-iron pipes of a growing water-works, whether discarded owing to lack of capacity, or due to being worn out, the residual or scrap value may be insignificant.

The "obligation to replace worn-out parts" goes with every public service property. No owner of such a property can escape this obligation.

The growth of this obligation is entirely independent and apart from the actual progress of the inherent deterioration of any article. Ordinary repair and adequate maintenance will keep the article during its life at 100% efficiency—as measured by the standard of the particular plant in question; but, though kept in this condition, there is a constant lessening of its probable remaining life, and it is this remaining life which determines the extent and the limit of the "obligation to replace or to renew" which the owner carries and which any purchaser will take into account, as stated, when estimating what he can afford to pay for the plant.

There is, therefore, no need of knowing whether the so-called "actual depreciation" follows a curve which drops slowly at first and more rapidly in the last years of service, or a curve which drops fast at first, or whether it follows a straight line. The only question which the valuation expert is called on to determine in the case of a valuation for purchase or sale is that of remaining life and the cost of replacement at the end of the probable life. These elements will be the measure of the "obligation to replace" which goes with the plant, regardless of whether the same remains in the hands of the original owner or whether acquired by a new owner.

The "obligation to replace" has heretofore been called by nearly all writers the "accrued theoretical depreciation" or simply "accrued depreciation" and frequently has been treated as though it had actually been a repayment of invested capital.

From an accounting standpoint, there are various ways in which theoretical depreciation may be estimated and applied in amortizing invested capital. It is unnecessary to review them. Considering physical properties alone, it is always true, on the assumption of permanency of unit costs, that the "present value" plus the "accrued obligation to replace" is just equal to the investment.

The owner is at all times entitled to a return at a fair rate of interest, both on the present value and on the obligation which he has assumed to keep the plant at 100% valuation. Consequently, when rates are to be fixed, there is no need of attempting to separate the investment into its two parts "present or depreciated value" and "accrued depreciation", of which the latter might better be called "the outside investment necessary to provide for replacements." There is nothing to be written off under this method of treatment from the capital account for "accrued depreciation"; the accrued depreciation being nothing else than an estimate of the amount of an "investment necessary to provide for replacements" and this may be regarded as the "accrued obligation to replace", expressed in dollars.

THE PRESENT OR REMAINING VALUE AS AN ELEMENT IN REGULATING RATES.

When a property is to be purchased, a prudent purchaser will make inquiry relating to the condition of the various parts, in order to ascertain the amount of deferred maintenance and the probable additional term that the perishable parts of the property will serve. He will also ascertain the probable cost of replacing each part, with due allowance for residual values. He will thus obtain a measure of the obligation, which he assumes, to replace worn-out parts and to keep the plant at 100% efficiency. He will, as here indicated, treat the "obligation to replace worn-out parts" just the same as he will treat deferred maintenance. Both of these items he will deduct from "cost to reproduce new." The remainder is what he can afford to pay for the physical plant.

There is, of course, nothing wrong in using the value of physical properties as determined in this way (practically investment-less-depreciation) as a basis for the regulation of rates, provided that methods are correctly and continuously applied throughout the entire life or probable life term of each perishable article; but there will be from year to year a change in the remaining life of the several

parts of a plant, with a consequent change of remaining value and a change in the annual depreciation increment. Computation by any method requiring an annual re-determination of depreciated value, becomes involved and complex, and by its volume burdensome.

It is to be hoped that these methods, and particularly the method recommended in the Report of the Society's Special Committee on Valuation, already referred to, will not be generally accepted, and that the simpler and exactly equivalent Sinking-Fund Method of valuing always at 100% of the investment, as set forth in the writer's valuation paper,* will be substituted for the Committee method, or that, better yet, the Unlimited-Life Method will be adopted whenever conditions favor its application.

Valuation at 100% of the Investment as an Element in Regulating Rates.

The application of these simple principles, which involve the assumption that no portion of the earnings is used to retire capital, but that a suitable part of the earnings will go into a replacement fund or into an investment for replacement purposes, can perhaps best be understood on the basis of an example:

An electric generator with a 20-year life may be used for illustration. Assume, in the absence of any accepted method of appraisal, that remaining value is determined by deducting accrued depreciation estimated by sinking-fund methods.

Suppose the generator to be a part of a light and power system, and suppose, further, that it has reached the last year of useful life and will have no scrap value. A purchaser will value the generator, if he estimates interest on a 6% per annum basis, at about 8.23% of its original value, and this is all that he will pay for it. He takes upon himself, when he buys the light and power plant, an obligation to replace the generator with a new one at the end of another year. He must then renew the investment represented by this article at 100 per cent. The obligation which he voluntarily takes upon himself at the time of his purchase to replace the generator in a year is 91.77% of the cost of a new generator. At the end of the life of the generator, he will have received in his earnings the last increment of the original investment in the generator, or 8.23% of its cost, and he will meet

* *Transactions*, Am. Soc. C. E., Vol. LXXV, pp. 770 *et seq.*

his obligation to continue in business by acquiring a new generator and thereby renewing the full original investment of 100% in this particular appliance.

It makes no difference whether there is only one generator, or whether there are twenty in use. The principle is always the same. Moreover, in such a simple case as that of twenty generators of all possible ages, each with a useful life of exactly 20 years, the accrued obligation to replace these generators when worn out (6% per annum interest being again used for purposes of illustration) will be 41%, as shown by the writer's formula.*

In other words, the remaining value of the twenty generators (cost less depreciation, as ordinarily noted) will be about 59 per cent. No purchaser would include the twenty generators in his valuation of the property at more than 59% of their aggregate cost; but he would, nevertheless, and with reason, expect to be allowed to earn interest on 100% of their cost new, claiming rightfully that he is entitled to the same rate of income return on accumulated annual replacement increments as he is entitled to earn on the rest of his invested capital. He will justify this claim by pointing out that the earnings on any accumulated replacement fund are not available for any other use than the replacement of worn-out property; that such earnings do not, therefore, represent income; and that it is for this reason he is entitled to have the aggregate annual replacement allowances, together with accumulated interest, treated as interest-bearing capital.

In this connection attention may be called to the laws of California,† which prescribe that the Railroad Commission (having the duties of a Public Service Commission)

"may from time to time ascertain and determine and by order fix the proper and adequate rates of depreciation of the several classes of property of each public service utility. Each public service utility shall conform its depreciation accounts to the rates, so ascertained, determined and fixed, and shall set aside the moneys so provided for, out of earnings and carry the same in a depreciation fund, and expend such fund only for such purposes and under such rules and regulations, both as to the original expenditures and subsequent replacement as the Commission may prescribe. The income upon investments of moneys in such fund shall likewise be carried in such fund."

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 780.
† Statutes of 1911, 1st Extra Session, Ch. 14, Sec. 49.

It is here apparently recognized that the depreciation fund is to be used for the specific purpose of replacing worn-out parts, and that, in regulating rates, consideration need be given only to the amount of capital reasonably and properly invested, without any deduction for depreciation.

The earnings, in other words, to be adequate, must include operating expenses of every character, a proper allowance for present and prospective replacements (so-called depreciation), and a reasonable income computed at the proper interest rate on the invested capital.

It has been amply demonstrated in the writer's paper on appraisal, that this method of valuing for rate-fixing purposes at 100% of the invested capital is identical in its results with Method No. 3 of that paper, which is the method of computing depreciation recommended in the report of the Special Committee on Valuation, and which, while apparently conforming to the Court decisions, is yet like others not strictly correct unless it has been applied from the beginning. When these methods have not found application from the beginning of operation, the transition is easy from either of them to the assumption that a public service property has unlimited life and that all replacements are to be treated the same as ordinary repairs and maintenance.

According to the system of valuing properties for rate-fixing purposes at 100% of the reasonable and proper investment, it is not necessary to ascertain the accrued depreciation or the equivalent amount that should be in a replacement fund, or that should be regarded as invested to provide for renewals. It is necessary, however, in estimating earnings, to determine how much thereof should be allowed to the owner to compensate him for assuming the obligation to replace. This, if estimated for a new plant under the Sinking-Fund Method, is the annual increment determined by sinking-fund compound-interest methods, which, in the years of the probable useful life at the same rate of interest as is earned (net) by the entire property, will amount to the cost of replacing the parts of the property when worn out.

The allowance for the obligation to replace, when operating on the assumption of unlimited life of the entire property, is the actual annual replacement requirement, which need not be closely estimated, because the surplus of any one year will be available for use in subsequent years.

If the owner of a plant of numerous parts and all possible ages is required to place all sums earned as "depreciation" or earned as a "replacement annuity", in a special fund, the theoretical balance on hand in such a fund will be, as here noted:

Under the Straight-Line Method of estimating amortization for plants of full growth, the accumulation will be 50% of the investment in perishable property; this accumulation is independent of the interest rate, and the earnings by this fund are of no concern to the rate-payer.

Under the method of estimating the "accrued obligation to replace" by the Sinking-Fund Method for old plants, with interest at 6%, and the hypothesis that actual life will conform to probable life,* the theoretical accrued obligation to replace will be:

For articles having			5	-year	life,	about	38%.
"	"	"	10	"	"	"	40%.
"	"	"	20	"	"	"	38%.
"	"	"	30	"	"	"	34%.
"	"	"	40	"	"	"	31%.
"	"	"	50	"	"	"	28%
"	"	"	60	"	"	"	25%.

These percentages apply strictly, of course, only to cases in which the age of the plant is greater than the life of its parts. They indicate the extent, however, to which an accumulating replacement or depreciation fund may exceed the demands on it. In some measure, approximating this unexpended surplus, such a fund is available for outside investments. Interest on the same, when it represents the obligation to replace, must be earned by the owner for the benefit of the plant; consequently, it makes no difference to what purpose he applies this surplus, provided only that ample assurance remains that replacements will actually be made when necessary.

When the capital is being amortized, the accumulations in the amortization fund are the absolute property of the owner. They are not subject to control by the rate-payer, yet, nevertheless, here, too, proper assurance may be expected that replacements will be duly made and it would not be unreasonable to expect an adequate fund to be maintained to meet emergencies.

* *Transactions*, Am. Soc. C. E., Vol. LXXV, formula on p. 784.

In order to show beyond all question that the method of valuing at 100% in fixing rates under continuous application from the beginning is correct and proper, an electric generator with a life of 20 years, which has served 15 years, may be taken as a basis for an illustration. The usual assumption is made, for the purpose of this illustration, that there is no change in the cost of this article during its life and that it will go out of service when exactly 20 years old. Interest in this illustration is taken at 6% per annum:

Equal-Annual-Payment Method.—(Always correct if applied from the day the article went into use.)

Original investment		$100.00
Life (new)	20 years	
Time in service	15 years	
Remaining life	5 years	
Accrued depreciation (= amortization to date)		63.27
Remaining value		36.73
Interest on remaining value	$2.20	
Annual depreciation or annual amortization increment for 16th year	6.52	
Required net earnings	$8.72	

In this case the depreciation in the 16th year is that amount which invested annually at 6% will retire the remaining value $36.73 in the remaining 5 years of life.

Sinking-Fund Method.—(Method No. 1, as explained in the writer's paper on Valuation.*)

Permanent investment		$100.00
Life (new)	20 years	
Time in service	15 years	
Remaining life	5 years	
Interest on the investment	$6.00	
Annual depreciation or annual replacement increment for any year	2.72	
Required net earnings	$8.72	

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 770.

Although it can thus be shown that for each year the earnings should be $8.72 on the $100 of original capital investment, a new calculation is necessary for each perishable article and for each year under the Equal-Annual-Payment Method, and for the rational Sinking-Fund Method a single simple calculation suffices for each group of articles of the same probable life term.

Effect of Inadequate Earnings.

Depreciation or replacement annuities are not ordinarily fully covered by the earnings in the early years of the life of public service properties. The cases in which earnings are adequate from the beginning to yield a proper interest return, together with the replacement annuity, are relatively few. Consequently, particularly if methods of appraisal other than the Unlimited-Life Method are insisted upon, there may be a period in the life of the public service concern during which a part of the so-called accrued depreciation will remain unrecovered. Temporarily at least, there will then appear to be a business loss; but a loss of the character which, in the course of time, should be amortized if the business enterprise is a legitimate one.

The United States Supreme Court, in Knoxville *vs.* Knoxville Water Company, says:

> "If, however, a company fails to perform this plain duty and to exact sufficient returns to keep the investment unimpaired, whether this is the result of the unwarranted dividends upon over-issues of securities, or of omission to exact proper prices for the output, the fault is its own."

In expressing this opinion, the Court has overlooked the fact that such earnings as it assumes to have been possible can rarely be realized at the beginning of a new business, and that there will be some years in the life of almost every public service concern for which it would be unjust to make so sweeping an assumption.

Although it would be improper to consider early losses, including deficient or unrecovered depreciation, in every case, as the exact amount to be amortized by future earnings, there is no doubt that due consideration should be given to such losses in order that, from the sum of experience, the world over, a proper basis may be established for making the necessary allowance therefor. This allowance, of course, can be in the nature of an interest-bearing addition to the invested capital.

It does not, strictly, represent value until a return thereon in the earnings is assured.

It is to be expected, therefore, that in the case of many public service properties the owner will have had no opportunity to make investments the earnings of which will meet his replacement requirements. When there has been such a deficiency of earnings, the ordinary method of computing the annual replacement increment by sinking-fund compound-interest methods, based on the original probable life or on the reduced value computed by any method and the remaining life, would be improper and inadequate. It is under such circumstances that recourse must be had to special methods of computing the depreciation or the annual replacement increment.

Unlimited-Life Method.

In such cases as those just referred to it may be necessary to provide for a replacement at the full cost of various parts in the remaining years of life, or of burdening the property with an allowance for the accrued deficiency of earnings, which is then to be amortized in a reasonable number of years.

When an appraisal is to be made, for rate-fixing purposes, of a plant which has continuously been operated with inadequate earnings, there is no escape from the conclusion that the investment has remained undiminished. It would be unreasonable not to concede to the owner his right to a return on the investment and also to allow him to earn enough in addition to meet replacements as they become necessary. Considerations of this character led the writer to adopt the Unlimited-Life Method as not only fair to both owner and rate-payer, but as the one method which has the peculiar advantage of requiring lowest earnings in the early years of operation when the rate-payers are fewest in number.

This method has the advantage over all the other methods that it is applicable regardless of past conditions. All the other methods, the Straight-Line Method of estimating depreciation, the Equal-Annual-Payment Method, the Sinking-Fund Method, are only then correct and equitable methods of making appraisals and of determining annual depreciation, or amortization increments, when they are properly applied from the beginning of operation. Their use assumes continuous appli-

cation throughout the entire probable or actual life of each part of a plant.

When the Court says that, if an owner fails "to exact sufficient returns to keep the investment unimpaired, whether this is the result of the unwarranted dividends * * * or of omission to exact proper prices for the output, the fault is his own", this fact is overlooked. It is time that the Courts revise such decisions, as they have already caused much trouble and no little juggling on the part of experts to secure justice for their clients.

There can be no fairer nor better way of determining the earnings of a public service property than that under which the owner is regarded as the agent of the public. He is then to be allowed interest on the investment which he makes as such agent, and he is also to be allowed whatever may be necessary for the up-keep of the property, maintenance, repairs, and replacements.

There should be no amortization of capital, no more than there would be if the rate-payers themselves made the investment without the intervention of an agent.

If this view is adopted, every public service property may be considered to have unlimited life. The property in its entirety is not subject to depreciation. Its appraisal at all times for rate-fixing purposes is at the full amount of the investment.

The earnings must be adequate to provide interest on the full amount of capital invested and also to meet the replacement requirements. The annual replacement requirement will be negligible in the early years of a plant's life, or in the early years of any single article; but this replacement requirement will grow as the plant acquires age. It can be tentatively estimated. All sums collected for replacements should be separately accounted for. Ordinarily, the replacement of larger units will be anticipated, and their cost will be distributed over a number of years, and, in the long run, particularly when a complex plant worth millions is under consideration, there should be no difficulty in estimating a fair average annual replacement requirement.

What Part of Earnings May Be Written Off Capital?

Under the impression that any sum collected under the designation "depreciation" or "amortization" is a repayment of a part of the investment, such sums are frequently written off from the in-

vested capital or from the "cost of reproduction new", which is an approximation of the invested capital.

This is correct:

1st.—When, from the beginning of the installation, the Straight-Line Method of estimating "amortization" or "depreciation" is applied and the amortization allowance has actually been earned.

2d.—When the actual amount of the annual decrease in remaining value has been computed by the Equal-Annual-Payment Method and earned from the beginning.

3d.—When any other definite scale of capital repayment is adopted such that in the life of the part the several payments "without interest thereon" amount to 100 per cent.

Value from Various Standpoints.

Under the Straight-Line Method of computing depreciation or of amortizing capital, the value for rate-fixing purposes, "cost-less-depreciation", is the same as value to a purchaser. This is self-evident.

Under the Equal-Annual-Payment Method, the appraisal for rate-fixing purposes is the cost, less accrued depreciation; and here, too, this value is the same as that which would be determined by a purchaser.

Under the Sinking-Fund Method, the appraisal for rate-fixing purposes is at 100% of the investment. It is assumed, under this method, that the replacement fund is intact and a part of the property. Thus considered, the property (including the replacement fund) has a value to a purchaser of 100 per cent. If he does not pay 100% and does not get possession of the replacement fund, then he must put it up himself, because he takes with the property, as has been explained, the obligation to replace, which, expressed in dollars, is the amount which should be in the replacement fund.

Under the Unlimited-Life Method there has been no return of capital. The appraisal is at 100% of the investment. The value of the property to a purchaser is 100%, because he takes the place of the original owner and is entitled to receive interest on the full amount of the investment. The earnings yield him interest on this amount, and he needs no replacement fund, because the replacements will be met out of earnings from year to year as they have to be made.

It thus appears that value for rate-fixing purposes and value to a purchaser can be reconciled, regardless of the method adopted for computing adequate earnings.

APPRAISAL MUST BE MADE WITH DUE REGARD TO PAST HISTORY OF THE PROPERTY AND TO PROBABLE FUTURE CONDITIONS.

A change from one method of computing allowable earnings to another is not always possible without injustice to either the rate-payer or the owner. If the Equal-Annual-Payment Method has been acceptable for a time and it is then determined to pass to the Straight-Line Method, there will be an immediate reduction of the interest-bearing portion of the investment. The cost-less-depreciation will be smaller under the latter than under the former, and the owner will be compelled to sacrifice a part of his investment without compensation.

If the Sinking-Fund Method has been used in computing allowable earnings and there is a change made to the Straight-Line Method, this will release the accumulation in the replacement fund, which is thereupon to be regarded as returned capital, but the replacement fund, whether it exists as a fund or has been otherwise used by the owner, will fall short of the accrued depreciation, as the same would have been estimated by the Straight-Line Method, and, consequently, the owner will again be unfairly deprived of a part of his investment.

If the Sinking-Fund Method has been used from the beginning of operation and a change is made to the Unlimited-Life Method, there may be an accumulation in the replacement fund, or there has been distributed to the owner from this fund a larger sum than is necessary to aid in equalizing the annual actual replacement requirements, and to this extent the owner would benefit by the change.

If operations have been conducted from the beginning on the basis of earning a proper interest return on the investment, plus the amount necessary from year to year to renew worn-out parts, and there is then to be an appraisal and computation of rates by any method other than the Unlimited-Life Method, this would be an injustice to the owner, because he has not in the past had the benefit of the larger earnings which he should have had under these other methods of computation.

All this is referred to, to show that the correctness of any method of appraisal for rate-fixing purposes is not predicated on the method alone, but on the continuous application of the adopted method from the beginning, and on the assurance that the same method will be continued in the future. The decisions of the Courts cannot change

this fact, and, where they have disregarded it, they will undoubtedly be modified in the course of time.

Comparison of Actual with Probable Life.

Attention has been called* to the fact that the expectancy of articles which remain in use, instead of probable life new, should be taken into account whenever an article has acquired some age and has survived the possible accidents of the early period of its life. In other words, it is proper to pay attention to the condition of the plant and to the condition of the articles of which it is made up when remaining value is to be estimated.

All estimates of annual depreciation and of accrued depreciation are based on premises which cannot be determined with accuracy. The probable life of any article when new and the life expectancy of any article which has been in use for some time cannot be determined with any great degree of precision. Consequently, all estimates of depreciation are only approximations.

There is so much uncertainty in such estimates, under the ordinary conditions under which public utilities are operated, that a wide range in the method of making the estimates has been the result.

When, therefore, the correctness of methods is under discussion, this fact should not be lost sight of. Nevertheless, the academic discussion which is being indulged in by the Engineering Profession is justified, because it will lead to an ultimate standardization of methods and finally to the general adoption of the most convenient and generally best method of making the valuation which is to serve as the basis for fixing rates fair to both the rate-payer and the owner.

Recognizing this limitation, and all the uncertainties that result from imperfect knowledge relating to the actual and to the probable life of the elements of any public service plant, and to the difficulty of determining the expectancy of those elements which have already been in use for some time, it is nevertheless important that the whole question be fully considered from the theoretic standpoint, in order that a framework may be constructed into which the best data furnished by experience can be fitted.

---

* *Transactions*, Am. Soc. C. E., Vol. LXXV, pp. 837-838.

The non-agreement of the actual life of individual items with the probable life and the extent to which this should be taken into account in estimating present worth and in estimating replacement requirements have, in line with this thought, been studied on various assumptions with interesting results. These will be briefly referred to, the tables that were prepared being withheld except as to final results until more definite information is available relating to the probable rate of failures from year to year with advancing age in any group of articles.

When any large number of articles which have the same probable life, as, for example, 10 years, are considered, there will be as many aggregate service years represented by the failures to reach the probable life term of 10 years as there will be service years represented by those articles which outlast the 10-year term. It may also be accepted as a certainty that there will be a greater number of articles per year to go out of use in the years just preceding and just following the term limit than at any other time.

This is in conformity with the law of probabilities.

On this hypothesis, with the assumption of failures according to the law of probabilities, but all within a period equal to twice the probable life, and on another hypothesis according to which a gradual uniform increase of failures up to the tenth year and thereafter a gradual uniform decrease of failures to the twentieth year—or to twice the probable life term, it was found possible to predict expectancy and also to compute the annual replacement requirement.

Unfortunately, there are no records available to justify the assumption that all failures may be assumed to occur within twice the probable life term. Nevertheless, the distribution of failures to the double term, with a greatest rate of failures at the end of the probable term, is certain to be far nearer the truth than the usual assumption of general agreement between probable and actual life. It may be proper, therefore, to refer to the results of the studies.

Under the assumption of failures according to the law of probabilities, it was found that an article having a probable life of 10 years when new should have the expectancies shown in Table 1.

On the assumption that the rate of increase in the annual number of failures is uniform from the beginning of service to the end of the probable life term, and that there is a similar uniform decrease

in the annual number of failures after the end of the probable life term, Table 2 has been prepared, and shows the expectancy for any surviving article that is still in good condition.

TABLE 1.—EXPECTANCY, ACCORDING TO THE LAW OF PROBABILITY, FOR AN ARTICLE WITH A 10-YEAR PROBABLE LIFE; ON THE ASSUMPTION THAT ALL ARTICLES FAIL WITHIN A PERIOD PRACTICALLY TWICE THE PROBABLE LIFE TERM.

No. of years.	Expectancy, in years.	No. of years.	Expectancy, in years.
1	10.00	11	2.71
2	9.00	12	2.42
3	8.05	13	2.18
4	7.11	14	1.97
5	6.22	15	1.80
6	5.40	16	1.64
7	4.78	17	1.50
8	4.04	18	1.25
9	3.52	19	1.00
10	3.08		

Although, under this hypothesis of failures, there may be considerable departure from the actual number of failures in any year, there can be no question that this hypothesis is a much nearer approach to the truth than the assumption that remaining value and accrued depreciation can be estimated from tables based on probable life without regard to the condition of an article under consideration.

TABLE 2.—EXPECTANCY ESTIMATED ON THE ASSUMPTION THAT, OF A LARGE NUMBER OF ARTICLES HAVING A 10-YEAR PROBABLE LIFE, THE MAXIMUM RATE OF FAILURES IS 10% IN THE TENTH YEAR, WITH A GRADUAL INCREASE TO THIS AMOUNT FROM THE FIRST YEAR AND A GRADUAL DECREASE FROM THIS AMOUNT TO THE TWENTIETH YEAR.

No. of year.	Expectancy, in years.	No. of year.	Expectancy, in years.
1	10.00	11	3.67
2	9.09	12	3.33
3	8.27	13	3.00
4	7.46	14	2.67
5	6.77	15	2.33
6	6.12	16	2.00
7	5.51	17	1.67
8	4.95	18	1.33
9	4.44	19	1.00
10	4.00		

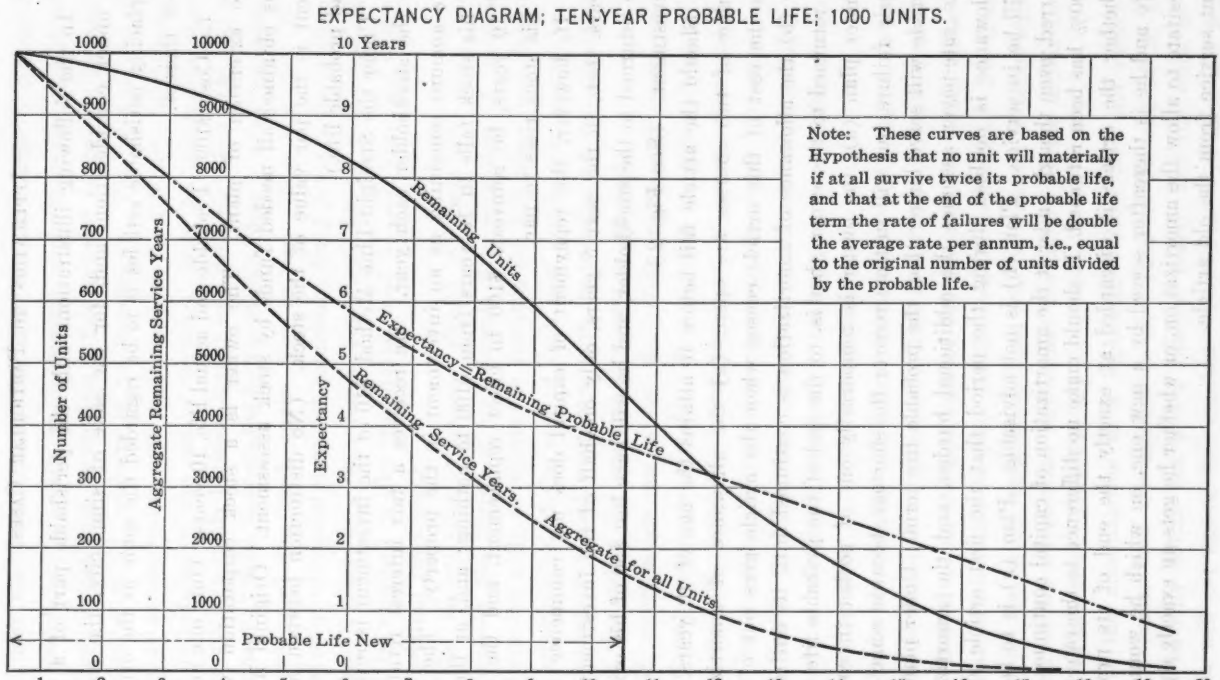
The basis for the results in Table 2 is shown diagrammatically in Fig. 6. The expectancy is found by dividing the remaining service years at any time by the corresponding number of surviving units. The reverse curve marked "Remaining Units" clearly indicates the hypothesis of failures on which the table is based. It is to be noted that, under this hypothesis, there is no serious departure from the results that were obtained by assuming that the law of probabilities would apply.

The replacement requirements, if failures occur substantially as assumed, would increase, for $100 of original investment, from $1 in the first year to about $10 in the ninth year, fluctuating thereafter between $9 and nearly $12 per year, and gradually settling down to $10 per year. For an annual investment of $100 per year (that is, for a growing plant) the replacement requirements would gradually increase from $1 per year in the first year to $463 in the fiftieth year, or from $1 per $100 of investment in the first year to $6.01 in the tenth year; to $8.16 in the twentieth, and to $9.27 in the fiftieth year.

In practical application, in other words, the annual replacement requirement in the case of a plant of full growth, all parts of which have a probable life of n years after the plant is n years older than any of these parts, will be about one-nth of their replacement cost.

In a plant which continues to grow, the annual replacement requirement will gradually approach, but can never quite reach, one-nth of the total replacement cost.

Although it may be granted that in the long run the failures of individual articles in any class will follow some definite law (perhaps a law similar to that which has been cited as more probable than failure always at the end of the probable life term), the fact remains that in no particular case, no matter how large a plant may be, will there be absolute conformity with any such law. Consequently, figures determined on the basis of any hypothesis of failures can be used to prepare smoothed-out curves, and from such curves tables for general use can be prepared. It is enough to know for the present that, ordinarily, it may be assumed that the replacement requirement of a large number of articles with a probable life of n years should increase progressively year by year to about one-nth of their cost in the nth year.



EXPECTANCY DIAGRAM; TEN-YEAR PROBABLE LIFE; 1000 UNITS.

FIG. 6.

Application to Particular Cases.

In the following illustrations only the perishable part of a plant is under consideration, and, for the sake of simplicity, the cost of replacing perishable articles is to be regarded the same as the original cost thereof.

1.—Cost, $100. Probable and actual life, 10 years. Only one article. No extension of plant. The owner is a stock corporation which has obtained all needed funds by stock assessment. Original investment is the par value of the stock. (No distinction between actual and probable life.)

Under the Straight-Line Method, $10 of the investment is returned to the stockholder each year. He receives a fair interest return on the amount remaining as an investment in the property. The value of his stock falls in 10 years from $100 to nothing; and, at the end of 10 years, he reinvests $100 to effect replacement, and the value of his stock rises to par.

If, however, the repayment of capital does not commence for 5 years, then, in the next 5 years, only one-half of the investment will be returned to the stockholder, and he will have lost $50 of his original investment. (See Fig. 2.)

Should the article fail before it attains the age of 10 years, then either of two courses are open: (a) the allowance of amortization on the cost of this article ceases when the article goes out of use; or (b) the allowance of amortization is continued until its entire cost is returned to the owner, that is, to the end of the probable life term. Under plan (a), the owner is temporarily out of pocket in case of early failure, but will in time recover the shortage, because some other article will serve longer than the probable life term. Under plan (b), the rate-payer assumes the additional burden, and the amortization allowance is doubled during the period that the first article should still be in service. Plan (b) is not advisable. Plan (a) is to be preferred, even though under it the amortization of capital continues after 100% has been returned. It should make no difference to the rate-payer whether the article is discarded at exactly the end of its probable life and he is thereafter served by a new one, on which he would not hesitate to allow the amortization, or whether he gets an exactly equivalent service from the old article.

Under the Equal-Annual-Payment Method, there is returned to the stockholder annually an increasing amount of the capital which he has invested and he receives a fair interest return on the amount remaining in the property as an investment. The value of his stock falls at an increasing rate as the end of the life term is approached, and is nothing at the end of 10 years. (On the assumption that no distinction is made between actual and probable life.) On the reinvestment of $100, contributed by the stockholders to effect replacement, the value of the stock again rises to par. (See Fig. 3.) If the repayment of capital does not commence for 5 years, then in the next or last 5 years on a 6% interest basis only $57.23 of the investment will be returned to the stockholder, and he will have lost $42.77 of his original investment.

The amortization allowance should continue for every article throughout the period of its probable life, regardless of whether it is discarded early or whether it survives the full term; and then, too, the amortization of the cost of each new article that replaces a discarded article should commence with its installation and should cease when the end of the probable life term is reached.

If amortization ceases for the article which fails early and is continued during the probable life term only for those which outlast their probable age—this being the limit of amortization tables as now in use—then the method is unjust to the owner. In other words, this method is difficult and uncertain in its application. Some improvement will result, however, in taking into account the expectancy at varying ages, as elsewhere explained.

Under the Sinking-Fund Method, the owner will be given an opportunity to establish a replacement fund, and if it be actually established and treated as an integral part of the property, the stock value will remain continuously at par. At the end of the probable life term of 10 years the entire replacement fund will be required to effect replacement, on the supposition again that the failure of the article occurs just at this time. (See Fig. 4.)

If the accumulation in a replacement fund does not commence for 5 years, then the amount in this fund at the end of 10 years will be only $57.23 (on a 6% interest basis), and the value of the stock will not exceed this amount. The owner will have lost $42.77.

It need hardly be stated that here, too, expectancy should be taken into account, when a determination of remaining value is to be made.

Under the Unlimited-Life Method, the replacement will be assured at the end of 10 years and the value of the stock at all times will be at par. (See Fig. 5.)

2.—Cost, $100. Probable and actual life, 10 years. Only one article. No additions are made to the plant. The owner is a stock corporation which has constructed the plant with money obtained by a bond issue.

Under the Straight-Line and Equal-Annual-Payment Methods, bonds are retired as amortization allowance is earned. The stock has only such value as results from an interest allowance in excess of the interest on the bonds, and no value if these interest rates are the same, and if, as assumed in this illustration, there is no surplus of earnings above interest on remaining investment, plus the amortization allowance. In case that the amortization is not earned for a term of years, the ownership of stock may become a liability instead of an asset.

Under the Sinking-Fund Method, the fund which is accumulating for replacements may be used for the retirement of bonds or otherwise. The stock will again have only such value as results from interest earned in excess of interest on bonds. In the case of earnings for a term of years, which are inadequate to meet the replacement annuity, the stock may be a liability instead of an asset.

Under the Unlimited-Life Method, bonds are refunded as they become due. The amount of outstanding bonds remains unchanged. The stock has only such value as results from the excess of interest earned when compared with the interest on the bonds.

It is obvious from these illustrations that, when works are constructed under bond issues, the earnings should exceed the interest on the bonds, in order to insure some compensation for management and the hazards of the business.

3.—Cost, $100. A single article with a probable life of 10 years. Interest, 6 per cent. With due regard to condition or to the departure of actual life from probable life.

Under the Straight-Line Method, the invested capital is reduced $10 each year. At the end of the 10-year term the article is found to be still in good condition; its expectancy is then probably from 3 to 4

years. The owner has already received back his full investment. There is no remaining investment, although the remaining value of this unit is from $30 to $40. By some hard and fast rule, the $10 per year payment should continue until the article is discarded, or by some other equally inflexible rule, as under illustrations (1) and (2), the $10 per year should continue until ten payments have been made, and should cease to be paid after the tenth payment. (See Table 3.)

20					

* At the beginning of the tenth year, the expectancy is 4 years, consequently, the remaining value of the article under the Straight-Line Method at $10 per year is $40.

In a 10-year life sinking fund table at 6% the remaining value for 4 years of remaining life is $47.08. The annuity, which will amount to $47.08 in 4 years, is $10.77. Interest on $47.08 at 6% is $2.82. The required net earnings, therefore, are $10.77 + 2.82 = $13.59.

Under the Equal-Annual-Payment Method, the remaining value at any time may be estimated from 10-year life tables, using the expectancy as an element in the calculation. If the probable life of the article new is used throughout, this should be done only under an inflexible rule, and all amortization should cease when the article

has reached the end of the probable life term, as under illustrations (1) and (2). If, however, the condition of the article is taken into account and its expectancy is determined, the remaining value will be about as shown in Table 3.

Under the Sinking-Fund Method, if computations are made with due regard to the expectancy of the individual articles, the required annual earnings will be uniform in amount and the same as under the Equal-Annual-Payment Method.

Under the Unlimited-Life Method, the investment again remains unimpaired, and whenever the article fails, whether early or late, it is replaced with a new one, the replacement allowance to be earned being the amount already noted, in order that funds may be available when the failure occurs.

4.—Cost, $100. Numerous articles. Probable life 10 years, some articles failing early, others serving after the end of the probable life term. The plant has full growth, and there are no further additions or extensions. All computations on a 6% interest basis.

Under the Straight-Line Method, the annual allowance for amortization will be $10. At the end of the 10 years, there will be some of the original articles still in service, possibly 45 to 50 out of each 100. The others, making up the original group, having an aggregate cost of $100, have failed and were replaced with new articles and some of these have failed and were replaced. The owner has received amortization in the sum of $100, and he has reinvested in replacements somewhat more than $60. The remaining investment, therefore, is about or a little more than $60. After the first 10 years have passed, the annual replacement requirement will be just about equal to the amortization allowance, and the remaining investment will continue at some amount somewhat in excess of $60. The required earnings on a 6% basis begin with $16 per year, gradually dropping to between $13 and $14.

Under the Equal-Annual-Payment Method, the appraiser will find himself in considerable difficulty, until the time is reached when the number of annual failures is fairly uniform. The extent of the amortization will then be about $30 to $40, and the remaining investment will be about $60 to $70. The replacement requirement in this case, also, will be just about equal to the annual amortization allowance, and the remaining investment will continue at about $60

to $70. (The required earnings will be uniformly and continuously $13.59 per year.)

Under the Sinking-Fund Method, with a replacement fund made up of equal annual replacement allowances computed by the Sinking-Fund Compound-Interest Method, there will be a gradual growth of this fund in 10 years, until the number of annual failures is fairly uniform, when there will be about $30 to $40 in the fund. Thereafter, the interest on this fund, together with the annual replacement allowance, will be about $10, which is the amount necessary to meet the annual replacement requirement. The required earnings are, from the beginning and continuously, $13.59 per year. The replacement fund will gradually grow until it contains about $30 to $40. This fund will be available for outside investments.

Under the Unlimited-Life Method, the $100 of original investment would remain unimpaired, and there would have to be provided a growing annual amount for actual replacements, beginning with about $1.00 the first year; $2.01, the second; $3.04, the third; and so on, to about $10 in the tenth year and thereafter.

5.—The case remains to be considered of a plant which has not attained full growth, and to which additions are made from year to year.

From a tabular comparison it appears that, when computed with regard to the expectancy of surviving articles, the application of the Unlimited-Life Method has the particular advantage of requiring lowest earnings in the early years, and the Straight-Line Method has the disadvantage of requiring the highest earnings in the early years; the Equal-Annual-Payment Method holds an intermediate position. The required earnings, computed on the hypothesis of failures as heretofore stated, would be $7.00, $16.00, and $13.59, respectively, in the first year; $120.12, $143.38, and $135.90, respectively, in the tenth year; and $283.18, $281.36, and $271.81 respectively, in the twentieth year.

Comparison of Methods.

When a municipality constructs improvements under a bond issue, suitable provision is made for the replacement of any of the worn-out parts of these improvements at the time that such parts go out of use. This is in strict conformity with the proceedings under the Unlimited-Life Method; but, in the case of the municipality, the

bond issue is also to be taken care of. The cost of the improvements is, in other words, to be distributed fairly to those who will benefit by them. This is usually done by fixing the term of the bonds so that the cost will be distributed over a sufficiently long period of time. The determination of this time period need not be in any definite relation to the life of the parts of the improvement. The improvement itself will usually be one that may be regarded as having unlimited life, such as parks, playgrounds, streets, and the like. When the term of the bonds of longest life has been fixed, on the basis of the probable life of the main elements of the improvements or otherwise, then a determination must be reached as to the best and most equitable rate of amortization.

This amortization may take place at a uniform rate per year, bearing heavily on present-day property owners—Straight-Line Method.

It may take place at an increasing rate per year:

(a) According to the scheme outlined under the Equal-Annual-Payment Method; or

(b) According to any arbitrary scheme that will approximate the compound-interest Sinking-Fund Method of estimating the annual amortization increment.

Or, it may be deferred for a time and then take place according to either of these methods.

In the case of a public service property constructed by a municipality, the amortization of capital usually begins at or soon after the acquisition of the property; and in the case of a utility constructed by a private owner, the amortization of capital should begin under the Straight-Line and Equal-Annual-Payment Methods at the beginning of operation, and, under the Sinking-Fund or the Unlimited-Life Methods, as herein fully explained, not at all during the continuance of private ownership.

In order to make clear how unsatisfactory it is to have to estimate "depreciation", or, strictly speaking, "the replacement requirement", according to any method except that of unlimited life, the diagrams on Fig. 7 have been prepared.

The curves here shown afford a comparison of replacement requirements determined according to some reasonable hypothesis relating to the expectancy of surviving articles, with the amortization allowance

(generally, though erroneously, called "depreciation") as the same would be determined by the Straight-Line Method and by the Equal-Annual-Payment Method. The replacement requirements represent the expenditures which are necessary from time to time for renewals to keep the plant in an efficient condition. The wide departure of these from the amortization lines determined by the common methods of estimating depreciation are made apparent by the diagram. Further comment is hardly necessary, except to say that, under the Unlimited-Life Method, the actual replacement requirements may be assumed to approximate Lines 1 and 3 for articles of the same probable life and the same age (plant of full growth), and to approximate Lines 2 and 4 for articles distributed in equal amounts to all possible ages (plant made up of uniform annual additions).

The Bonding Value.

The capital invested in the perishable parts of public service properties may be regarded as made up of the present value of these parts plus the theoretical accumulation in a replacement fund. The theoretical accumulation in a replacement fund is ordinarily referred to as the accrued depreciation.

The actual accumulation in a replacement fund may depart materially from the theoretical accumulation. The theoretical accumulation, estimated by sinking-fund methods, for a plant of numerous parts equally distributed to all possible ages on a 6% interest basis, will be between 25 and 40% of the investment, which, in the case of properties such as water-works or railroads, with values of many millions of dollars, will probably never be fully realized, because any large accumulation would be reinvested. Even the distributed portion of this fund is a part of the owner's obligation to replace worn-out parts.

The actual replacement fund, which should be maintained large enough to meet all calls on it for replacements, is usually a small part of the theoretical fund.

Any part of the theoretical replacement fund may be invested in outside securities or enterprises, but earnings thereon at the property's net rate of earnings should be regarded as made for the benefit of the property. Earnings by this outside investment, to the extent that it would earn a return if kept in the property, can be used for no

other purpose than to make replacements; consequently, the entire theoretical replacement fund may be regarded as a part of the owner's investment in the public service property.

The surplus in the replacement fund is sometimes distributed to the stockholders when the owner is a corporation; but, when thus distributed, it is not a dividend, because it reduces the value of the stock. When the distribution is made, whether under the name of dividend, or not, the fact remains that the obligation of the individual share of stock to replace worn-out parts is thereby increased and that any such increase of the obligation must carry with it a lessening of worth.

It is not correct to consider an annuity which, together with interest compounded annually, will, within the probable life term, amount to the cost of a perishable part of a plant, when collected annually under the name "depreciation" or under any other name, to be a repayment of invested capital.

When the depreciation or replacement annuity is thus computed, the investment remains at 100% regardless of what is done by the owner with the accumulating depreciation or replacement allowances.

A bond issue should never exceed the present worth, as the present worth of any property would be determined by a purchaser; consequently, the valuation of a property as a basis for a bond issue should take into account the method under which required earnings are computed. When the Straight-Line Method or the Equal-Annual-Payment Method has found application from the beginning, the valuation as a basis for a bond issue should include the "cost to reproduce the physical properties new less the accrued depreciation". So, too, when the Sinking-Fund Method has found application from the beginning, but without the actual establishment of a replacement fund, the outstanding bonds should not exceed the cost to reproduce less the "accrued replacement obligation", or, what is the same, less the accrued depreciation.

When, however, the appraisal is made on the assumption of unlimited life and the owner is assured a fair interest return on the full amount of his investment besides replacement allowance as the same becomes necessary, the property will have a 100% bonding value, as all extensive, complex, public service properties should have.

Bonds should be retired at least at the same rate at which the amortization allowance in the earnings will retire the investment, or,

in the case of the Sinking-Fund Method, at the same rate at which the obligation to replace grows.

In a property all parts of which have a limited life, when earnings are estimated on any other assumption than that of unlimited life for the entire property, the outstanding bonds may approach the 100% limit when the property is new, but should gradually fall to about 60% of the cost to reproduce new when the plant has reached an age greater than the probable life of any of its parts.* If bonds are issued in excess of this amount, and the property is turned over to the bondholder to cancel the obligation, he would find the value of the property inadequate to meet the indebtedness with which it is burdened; the bonds could not maintain a par value.

There are, of course, cases where bond issues are required to replace worn-out parts. In such cases the funds provided by the bond issue restore the particular parts which are replaced to a 100% value, and this full value, and not the remaining value of the old parts, at the time of commencing proceedings for the issue, is the proper basis on which to determine the permissible limit of the issue.

The use of the "replacement" or "depreciation" fund for retiring bonds is a proper use. It makes no difference whether any large surplus in this fund is allowed to accumulate, and is invested in interest-bearing securities, whether it is used in extending the plant, or whether it is used to discharge a debt on which the owner is paying interest, provided only that an adequate portion of the fund is readily convertible when required to pay for replacements.

Special Notes.

It is evident from what has here been presented that any attempt to estimate the amount of amortization allowance which should be made, to keep pace with the theoretic depreciation, is, at its best, only a crude approximation; that, if the plan to be followed is one which is to deal with depreciated value and not with the full investment, care must be exercised, not alone in adopting a method of making capital repayments, but also in determining how much of past earnings can be construed as having been applied, first to amortize early losses, cost of establishing business, and, second, to amortize capital, and in determining therefrom the remaining investment.

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 784.

To avoid these uncertainties and to establish a better relation of the earnings of the utility to the ability of the rate-payer to pay, recourse should be had to the method of valuation designated as the Unlimited-Life Method, whenever applicable, thereby eliminating all necessity for close approximations of depreciation. This method has easily recognized advantages, both in the case of old, well-established properties, and in the case of properties hereafter to be established.

In fixing rates, if amortization of capital is determined on, cognizance must be taken of the adopted plan of amortization.

Either (A), the amortization continues during the actual life of the article whether less or greater than its probable life new;

Or (B), the amortization ceases at the end of the probable life term, regardless of whether the article covered by the amortization has failed early or whether it continues in use long after the end of its original probable life term.

These are correct methods of amortizing capital, whether in uniform annual amounts, in increasing annual amounts, or according to any other plan.

When franchises have a definite time limit, at the end of which the plant is to be disposed of to the public, there may be some special provision for the transfer. If the transfer is to be made without any payment at the end of the franchise term, or at any elected time under a franchise with indeterminate life, then the invested capital should be returned during the time that the plant is in private ownership. If, on the other hand, the transfer is made, as it should be, on the basis of an investment by the public in the property at the time it is taken over, then the remaining investment should be determined according to the appraisal method that has been in vogue during the life of the property, and this remaining investment, which may be 100% under the Sinking-Fund and Unlimited-Life Methods, or less than this under other methods, will be the amount which the original owner should receive.

The past history of a public service property should always be taken into account when an appraisal is made which is to serve as a basis for fixing rates. It is unjust to assume that a part of the investment has been amortized unless the records or other satisfactory evidence shows this to have been the fact.

When rate-regulating bodies, such as Public Service Commissions, lay down rules requiring appraisals to be made of depreciated value (particularly when amortization, under the guise of depreciation, is subtracted from cost), grave injustice may result therefrom to the owners of established public service properties, and it is notably in such cases that experts exercise their ingenuity to bolster up values.

There are difficulties all along the line when appraisals are made by any other than that which has here been called the Unlimited-Life Method.

Depreciation is not amortization. It has nothing to do with the repayment of invested capital, and should always be considered apart from amortization.

It is difficult, usually unnecessary, and almost impossible to compute accrued or current depreciation correctly.

It is generally undesirable to amortize the investment in a privately owned public utility.

It is undesirable and yet sometimes necessary to include in appraisals value for intangible elements, such as early losses, or cost of establishing the business, as is frequently done, particularly when depreciated values are used as a basis for determining allowable earnings.

It is undesirable to permit appraisals for rate-making that will cause fluctuations in earnings, except only such as show a gradual increase of aggregate earnings, keeping pace, as time goes on, with the increasing number of rate-payers.

The service rendered should be at all times up to an established standard, and the price of the service should be fairly stable, with a downward rather than an upward tendency.

The bonding value should be as stable as circumstances will permit. This is secured by adopting the Unlimited-Life Method of making appraisals for rate-fixing purposes whenever it is applicable.

The Equal-Annual-Payment Method should be regarded as impracticable, except under inflexible rules making probable life the prime consideration, or requiring that due regard be had to expectancy. In the former case, the amortization will begin for each new investment as made and will continue for the assumed probable life term and no longer. Then, under such a rule, there will be times when amortization will be allowed on some article already out of service

at the same time that the cost of the article which replaces it is being amortized, and there will be other times when the cost of an article is completely amortized, and no amortization installment is to be provided for. Where single articles, or plants made up of very few articles, are under consideration, the undesirability of such a rule is apparent. Under the alternative rule, the method becomes difficult and inconvenient to apply. The Sinking-Fund Method is always to be preferred.

There are cases, as, for example, in a steamboat business with only one steamboat in service, where the advantages of the Sinking-Fund Method, as herein explained, over the other methods of appraisal, are readily apparent.

The Straight-Line Method is generally undesirable, because, if applied from the beginning, it entails early high aggregate earnings which must be collected from only a few rate-payers, and because its application is only correct when it has been in continuous use from the beginning.

The Unlimited-Life Method makes all considerations of depreciation, except for the purpose of tentatively approximating replacement requirements, unnecessary. It reduces the services required of valuation experts and accountants. It should be insisted on by the owner whenever it is applicable, and it should be elected by the rate-payer because it is fair and will make the required earnings least in amount when there are fewest rate-payers, that is, in the early years of operation.

The decisions of the Courts in defining fair value and in declaring for depreciated value are not to be taken as conclusive. They will be modified when these matters are better understood.

REPORT ON A SERIES OF TESTS ON CONCRETE COLUMNS REINFORCED WITH A SPIRAL OF STEEL.

Discussion.*

By C. G. Wrentmore, M. Am. Soc. C. E.†

Mr. Wrentmore.

C. G. Wrentmore,‡ M. Am. Soc. C. E. (by letter).—The denunciation by Mr. Godfrey of the column reinforced with longitudinal rods is more emphatic than is considered to be justified by either our experience or by the results of analysis, so far as the latter can be applied. These tests were begun more than 7½ years ago, and prior to that time the writer had concluded that for such columns the treatment then current was unsound, and that he would make no further use of them except with thorough hooping.

There are cases, however, where the use of longitudinal rods in members designed primarily for compression is justified. The writer's experience in the Philippines, where high wind pressures and mild earthquake shocks are frequent, and where violent earthquakes may be anticipated, at least in some localities, has demonstrated that reinforced concrete is peculiarly well fitted to withstand the resultant stresses. Although he would use longitudinal rods to resist the bending stresses, they would not be included in designing for direct compression, except where hooped at frequent intervals.

Neither is the writer inclined to concur in the logical conclusion derivable from Mr. Godfrey's statement that "though the Profession has been in possession of this experimental demonstration for a number of years, the facts have been so perverted, and recommendations

* Continued from April, 1914, *Proceedings*.
† Author's closure.
‡ Manila, Philippine Islands.

Mr. Wrentmore.

have been so utterly contrary to what they have shown, that standard methods of constructing columns are criminally bad." It is undoubtedly true that in the past, much work has been done, in reinforced concrete, which is unsound, and that in the future, faulty designs may be drawn; but the possibilities and limitations of reinforced concrete are not to be learned in a day, and the Profession is rather to be congratulated that the history of its use shows so few failures, than to be accused of a lack of either acumen or honesty in the interpretation of experimental data.

As to Conclusion (5) of the paper, that "The limit at which the first visible sign of failure occurs is raised by spiral reinforcement. This effect is greatest in short-time tests, and is perceptible for all percentages of reinforcement": Mr. Godfrey says (after reducing certain loads to unit stresses on the full section of the hooped column, instead of on the core) "if these facts teach anything at all, they blazon out the truth that hooping has no influence whatever on the first failure of a column * * *".

The writer holds that the tests, as given, demonstrate: (*a*) If the sectional area of the hooped column is taken as the effective area, Conclusion (5) is plainly true; (*b*) If the sectional area of the hooped column is taken to include the concrete outside the hooping, the long-time tests show no increase due to hooping, but the short-time tests show an increased strength which is greater with the larger quantities of steel. In Table 8, the writer compares the unit stress at first sign of failure of the columns of the various groups, basing it on the full section of all columns.

TABLE 8.—UNIT STRESS AT FIRST SIGN OF FAILURE.

Group.....	1	2		3		4		5		6	
Percentage of reinforcement.....	0.0	0.44–0.54		0.67–0.86		0.16–1.35		1.41–1.69		2.02–2.32	
Age.	Stress.	Age.	Stress.	Age.	Stress.	Age.	Stress.	Age.	Stress.	Age.	Stress.
40	1 089	35	1 650	46	1 578	45	1 970	51	1 980	42	2 020
68	1 796	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....
313	2 763	336	2 495	345	2 490	365	2 781	277	2 980	393	2 100
428	2 903	.....	.....	.....	.....	.....	.....	.....	.....	.....	.....

Table 8 shows that not only for an age averaging roughly 45 days is the strength increased by hooping, but also that this increase is very considerable, the smallest amount shown being that of Group 3, where it is 45% for from 0.67 to 0.86% of steel. (The 1 650 of Group 2 is given by a single column, and is abnormally high.)

Mr. Wrentmore.

For this age the lowest value for a single column is 1 650 for Group 2; 1 255 for Group 3; 1 330 for Group 4; 1 915 for Group 5; and 1 680 for Group 6; and the minimum for Group 1, plain columns, is 815; so that, if minimum values are taken, the increase is 54% with from 0.67 to 0.86% of steel. Moreover, Mr. Godfrey says:

"Hence the 'first sign of failure' is the function that must govern in safe design. This value, in these tests, runs from 1 400 lb. per sq. in. up, on the full area in compression, on the hooped columns, or 1 800 lb. on the core."

The hooping will be more effective in raising the first sign of failure as the modulus of elasticity decreases, or, more exactly, as the deformation under a given unit load increases. This would result in a greater effect in a weak mixture and also in green concrete, and less in a strong mixture, and would gradually decrease with age. As the tests show that the increase is about 45% at 45 days, it should be expected that for 20 or 30 days, it would be even more.

The fact that economy calls for stripping the forms at an early date, that under actual working conditions they are frequently removed as early as 14 days, thus throwing the load on the concrete while the elastic modulus is still quite low, makes this increase of the limit of first sign of failure especially useful.

The weakness of the concrete at this time is due to the weakness of the cement, and supplementing the bonding action of the cement by the use of a spiral of steel, the strength of which is accurately determinable while that of the green concrete is always questionable, gives the structure an insurance against failure at the time when failures have usually occurred. The large deformation which may occur on stripping forms from a concrete which is slow in hardening, throws the spiral into stress, and so puts it in condition to exercise a greater influence at any later date. Again, the percentage of ultimate strength at which the first sign of failure occurs is lower at the earlier age, and this fact acts as an insurance to workmen, plant, and building against an abrupt collapse without any warning. Such collapse involving an entire structure, may result from weakness in, or overloading, a single column; whereas, if the member, by flaking or spalling, had given warning that failure was impending, much damage might have been averted. It is under precisely these conditions that the column with longitudinal rods is especially undesirable, as the large deformation of green concrete induces high compressive stresses in the steel which tend to cause buckling, so that the steel may actually weaken rather than strengthen the column, unless the rods are hooped at frequent intervals.

The relation of ultimate strength to first sign of failure is of interest only in so far as it may prove to be an insurance against loss of life or property by giving warning of imminent failure. No

Mr. Wrentmore.

engineer can be sure that his structure will not at some time, through ignorance or carelessness, be subjected to loads in excess of those for which it was designed, and it is not undesirable that in such case the structure be capable of giving warning of its overstressed condition rather than to fail abruptly.

Mr. Buel's inquiry regarding the method of determining the value of E is answered fully in the paper. An examination of Fig. 17 will suffice.

SOME PRINCIPLES RELATING TO THE ADMINISTRATION OF STREAMS.

Discussion.*

By Robert E. Horton, M. Am. Soc. C. E.

Mr. Horton.

Robert E. Horton,† M. Am. Soc. C. E. (by letter).—This paper presents an argument in favor of the extension of the doctrine of priority in the use of streams, as now adopted, to some extent at least, in the Western United States and other irrigation countries, so as to include in this practice the eastern part of the United States, where the doctrine of riparian rights generally prevails. The writer feels obliged to take exception to some of the author's arguments and conclusions; at the same time, it is recognized that there is vast need for improvement in riparian law and practice regarding water rights in the Eastern United States. How this may best be brought about is a problem yet to be solved. In one thing the writer agrees most heartily with Mr. Johnston, and that is that some system should be devised by which the tedious and expensive litigations now prevalent, both in the East and West, can largely be obviated. The writer also agrees with the author (and believes that most engineers in the East who have had wide experience in water litigation will also concur in the opinion) that many of the so-called judicial questions arising in water-right decisions could be settled far better by engineers, under certain judicial restrictions, than as they are at present by the Courts. The writer does not mean to cast any reflection on either the judicial or legal fraternity; perhaps the blame rests as much with the Engineering Profession as anywhere; but it is a fact that many water-right litigations resolve themselves, in simple language, into a war of experts, decided by a referee who is not competent, through

* Continued from October, 1914, *Proceedings*.
† Albany, N. Y.

Mr. Horton.

knowledge, training, or experience, to judge exactly the merits of the contentions of either side. It has happened a number of times in the writer's experience that after a tedious and costly litigation over questions of water rights, a decision has been handed down by an entirely impartial judge or referee—a man of the highest ability from a legal standpoint—which was almost wholly incapable of practical application and required another lawsuit to decide the decision.

Looked at from an Easterner's viewpoint, it seems to the writer that the doctrine of priority, as applied to water rights, is fully as pernicious as the doctrine practiced in the East appears to the author. If the doctrine of priority is good, then the argument advanced by Mr. Johnston, that municipalities should be given the right to divert water from streams without compensation to vested power or other riparian interests, does not appear to be sound. The power interests are generally there first. If priority of use is a sound basis for establishment of right, then their rights are established thereby, and they should not be dispossessed without remuneration. The writer believes that in many instances vested interests have grown up in a manner inimical to public interest, and that curbing and regulating the use of public waters is necessary, but it must not be forgotten that the upbuilding of industrial welfare in the East is in a considerable degree the result of the utilization of water power by individual enterprise in early times, when land and water rights were unsalable or of little value.

The public has received, through taxes and other indirect benefits, enormous remuneration for the utilization of these rights, and, in the majority of instances, the writer fails to see where there is any large element of unearned increment in value appertaining to the occupant or reputed owner of such rights.

Municipal governments are notoriously lacking in foresight in securing adequate sources of water supply. Suppose a city has grown to a population of 100 000 during the past century, has outgrown its existing sources of water supply, and must now take a new source from some large stream which, heretofore, has been developed extensively for power purposes. The writer cannot see any element of justice in a doctrine which would permit the municipality at this late date to seize without remuneration holdings on this stream, and divert the waters to its own uses. Had the city administration a century ago exercised the same foresight which was exercised by private enterprise in acquiring rights on the stream, then the present necessity for acquiring such rights after their intensive development by private enterprise would not exist. On the other hand, excessive awards undoubtedly have often been made in cases of municipal diversion from power owners. Legal barriers and obstructions have been placed in the way of a municipality seeking to secure better water

supplies. To some extent public health has no doubt been jeopardized thereby for longer or shorter periods. This condition is primarily chargeable to the fact that all humanity is more or less human, and, being so, is greedy, grasping, and tenacious of its holdings; but, at the same time, it is believable that vast improvements could be made in methods of adjusting differences between municipalities seeking to divert water, and the owners of power interests affected thereby. The author's suggestion, that this can be accomplished through the utilization of engineers as arbitrators, with certain judicial functions, seems to be a good one. This method has not infrequently been tried in the East, and, so far as the writer has observed, the results have generally been more satisfactory, more promptly attained, and far less costly than when the usual condemnation proceedings have been followed. Mr. Horton.

The principal sources of litigation regarding water power, riparian rights, and diversion, in the East, as they have come under the writer's observation, are as follows:

1.—Land titles.

a.—Questions as to boundaries of grants on and along streams: whether they run to the bank or center of the stream, etc.;

b.—Questions of interpretation of terms used in land boundaries along streams, such as the "thread of the stream", "low-water mark", "ordinary stage", "high-water mark", etc.

2.—Flowage.

a.—Back-water from one dam affecting up-stream interests within the stream channel;

b.—Flooding of lands adjoining streams.

3.—Diversion.

a.—By municipalities, as against water-power and riparian owners;

b.—As between owners on opposite banks of the stream;

c.—As between different owners on the same dam or power canal.

4.—Interpretation of grants.

Different classes of cases arising will be discussed later.

5.—Priorities and surplus rights.

6.—Prescription, abandonment, and unlicensed use.

7.—Transference of riparian rights, change in character of use, etc.

8.—Pondage and storage, or other interference with the natural regimen of the stream.

In the writer's opinion, litigations arising out of the interpretation of grants would not be mitigated in any way by the adoption at the present time of the doctrine of priorities.

Mr. Horton.

The writer believes that existing grants, made years ago and indefinite in character, cannot now be reduced to simple terms, except by the tedious processes of litigation or by arbitration by a board of competent engineers. As illustrating the kind of questions arising from such grants, the usual language in which water was granted in the early days for power purposes at Eastern mill seats is briefly analyzed as follows:

1.—Enough Water for a Specific Purpose.—Grants of this kind have various degrees of indefiniteness, as, for example, quoting from the writer's experience: "Enough for a forge shop"; "enough for a saw-mill"; "enough for a woolen mill 20 ft. by 30 ft."; "enough to drive all the machinery which can be economically used in a cotton or woolen mill four stories high"; "enough for a fulling mill and oil mill, a carding mill, and enough to run a pump." The most common form of such grants was the use of the expression "enough water to drive one run of millstone." Grants of this kind were more or less indefinite. In some cases, the size and speed of the stone, kind of grain, and number of bushels to be ground per hour, were all stated. Such grants were capable of very definite interpretation. In many instances it is specified in such a grant that it conveys also enough water to supply power for the necessary machinery appurtenant thereto. In the majority of cases all that is stated is that the grant conveys enough water for a run of millstone, although the most common qualifications are the size of the stone, and whether or not power for attendant machinery is included.

2.—Enough Water for a Specified Water-Wheel.—Water rights in this language arise:

a.—From original grants;
b.—From prescription;
c.—From later interpretations of early indefinite grants.

Grants in terms of water enough for a specified water-wheel, if the wheel is a turbine of recent type and standard construction, are fairly capable of accurate interpretation. Unfortunately, however, many cases arise where the interpretation is difficult, as, for example, the grant of "enough water for a 40-in. Johnson re-acting turbine wheel as same was constructed in 1842." There were several types of Johnson wheels in use at about that time, and not all of them are the inventions of the same Johnson. Another grant which produced a litigation covering fifteen years, conveyed "enough water to drive three 6-ft. central discharge water-wheels." Grants conveying enough water for an overshot water-wheel 10 ft. in diameter, length not specified, and the like, are fairly common.

3.—Grants in Terms of Definite Fraction of the Flow of a Stream or Canal.—These are capable of interpretation if the capacity of the

canal or the economical basis of power development in the stream are determined. Mr. Horton.

4.—Grants in Terms of a Certain Number of Square Inches.—In order to distinguish this term from miner's inches, it may be defined as a certain number of millwright's inches. This term was applied to the vent or capacity of water-wheels, and, when thus used, invariably meant a stream of water of the actual area specified, flowing with a theoretical velocity due to the head. However, when the term came to be applied to the definition of water rights, openings in flumes, etc., disputes arose as to whether it meant actual square inches of stream or square inches of opening, that is, whether or not a coefficient of contraction was to be applied. This question has been the source of many large and costly litigations.

5.—Enough Water to Fill a Certain Pipe.—Efforts to interpret grants of this kind illustrate the necessity for technical or hydraulic knowledge on the part of those intrusted with their interpretation. This was forcibly brought home, in one instance, by the engineer being asked by the Court how large a pipe a certain quantity of water would fill, after witness had stated the quantity of water to be diverted from a stream in terms of gallons per 24 hours.

6.—Grants in Terms of the Right to Take the Flow Through an Opening of Specific Dimensions.—Grants of this kind are productive of litigation as to form of opening, question of contraction, etc.

It is rare to find a water grant in the East in terms of cubic feet per second, or cubic feet per minute, or other definite language. As illustrating apparently the maximum degree of indefiniteness capable of being promulgated in a grant of land and water, the following approximate quotation is made from a deed of a water lot in Northern New York, a copy of which is in the writer's possession. The deed describes a parcel of land granted by bearings and distances, and ends thus: "thence S. 28° W. 10 chs. 44 lks. to the southwest corner of the house now occupied by the widow Hawkins, be the same more or less." This deed was drawn by an old-time country surveyor and engineer, subject, apparently, to lapse of memory under certain trying circumstances, whereby he omitted to specify the acreage in this case.

As a matter of curiosity, the writer compiled the principal causes involved in some fifty water cases within his experience. The results are as follows: back-water, 8 cases; interpretation of grants, 8 cases; diversion, 14 cases; appropriation, 17 cases; and other causes, 3 cases.

Diversion and appropriation should properly be classed together; they comprise 60% of the total. This suggests forcibly the necessity of better methods in handling diversion cases than those now prevailing.

SUBAQUEOUS HIGHWAY TUNNELS.

Discussion.*

By Duncan D. McBean, Esq.

Mr. McBean.

Duncan D. McBean,† Esq.—Mr. Snyder gives a cross-section of the Harlem River Tunnel (Fig. 24), and sections showing the working platforms (Fig. 25), which, for convenience, were used instead of scows in constructing the subaqueous working chamber in which the tunnel was built. In discussing the method of constructing the tunnel, Mr. Snyder writes of it as being "a variation of the coffer-dam method", which is not only a misnomer, but also misleading. The patent obtained by the writer for this method is for a "Subaqueous Working Chamber"; he believes, therefore, that the method should be designated the Subaqueous Working Chamber method.

The advantages of this method are not only those accredited to the Detroit River method by Mr. Snyder, that is:

"That a structure can be placed at a higher level than with a driven tunnel, with a consequent reduction in the gradients of approach, and the section can be given a shape conforming to the use to which the tunnel is to be put, without being limited to the circular section usual with a shield";

but it also has many other advantages, some of which are as follows:

In cases where the circular form is desirable, instead of having a metal shell completely encircling each tube, it permits of joining the upper and lower segments of the metal shells to a vertical partition wall between them, thereby forming a twin-tube tunnel, and very materially reducing the quantity of materials required and likewise greatly reducing the surface of metal shells exposed to hydrostatic

* Continued from October, 1914, *Proceedings*.
† New York City.

Mr. McBean.

pressure; it enables the excavation to be made to the neat width and depth required for the structure; and it permits of placing all the masonry, both outside and inside the metal shells, in air.

The water-proofing can be placed on the outside of the masonry, thereby permitting the utilization of all the structural masonry to withstand the surrounding hydrostatic pressure, and thereby greatly diminishing the quantity of material necessary to overcome the buoyancy of the structure during construction.

Mr. Snyder shows a cross-section of the Detroit River Tunnel (Fig. 28), but it is submitted that his conclusion, that

"The method used in constructing the Detroit River Tunnel has been described so thoroughly in the paper by W. S. Kinnear, M. Am. Soc. C. E., and in the paper by W. J. Wilgus, M. Am. Soc. C. E., that but little comment is necessary,"

finds scant support in the papers* referred to.

An analytic examination of the several papers describing the construction of the Detroit River Tunnel shows: That sections of concrete forms consisting of the metal shells for inner forms, with vertical walls of sheeting attached thereto for outside forms (which, taken together, may properly be called sectional skeleton frames of a subaqueous working chamber), were lowered into the dredged trench and rested on temporary supports under the ends of the sections.† These temporary supports consisted of grillages supported by piles, or as Mr. Kinnear calls them,‡ "a 10 by 10-in. timber leg, or spud, about 10 ft. long, which was driven into the clay by an ordinary pile-driver drop-hammer * * *". Under the skeleton frame when resting on its temporary supports, the distance to the bottom of the trench varied "from 1 to 6 ft., according to the depth of trench left by the dredge."§ The foundation concrete under the skeleton frame was deposited through tremie pipes in the water on the muddy bottom of the trench. In order to use tremie pipes for depositing the concrete in the water under the structure, it was necessary to place the tubes 3 ft. apart and to encircle each tube completely with a metal shell, thereby not only causing the track centers in the completed tunnel to be 26 ft. 4 in. apart (in the Harlem River Tunnel the distance between the track centers is only 12 ft. 6 in.), but also increasing the buoyancy, to overcome which necessitated the placing of a large surplus of concrete on the outside of the metal shells. The skeleton frame around the outside of the metal shells was then filled with concrete through tremies, thereby completing the side-walls and roof of a subaqueous working chamber. The water within the metal shells

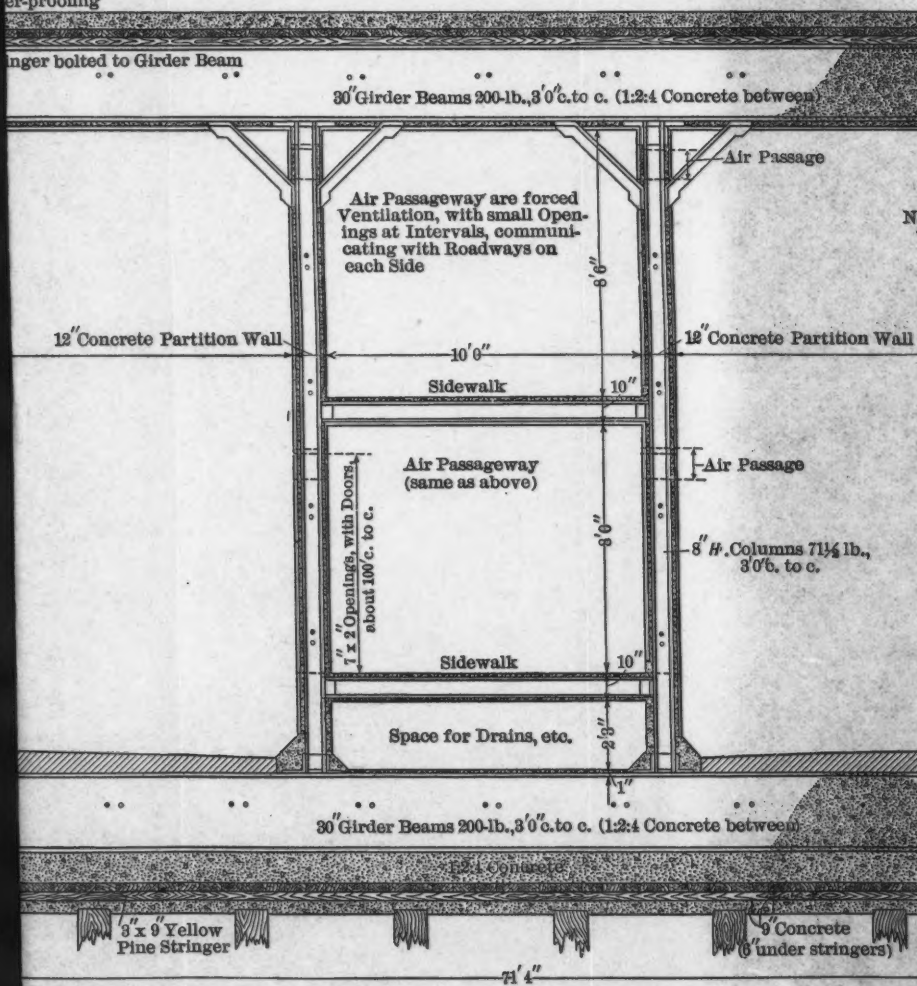
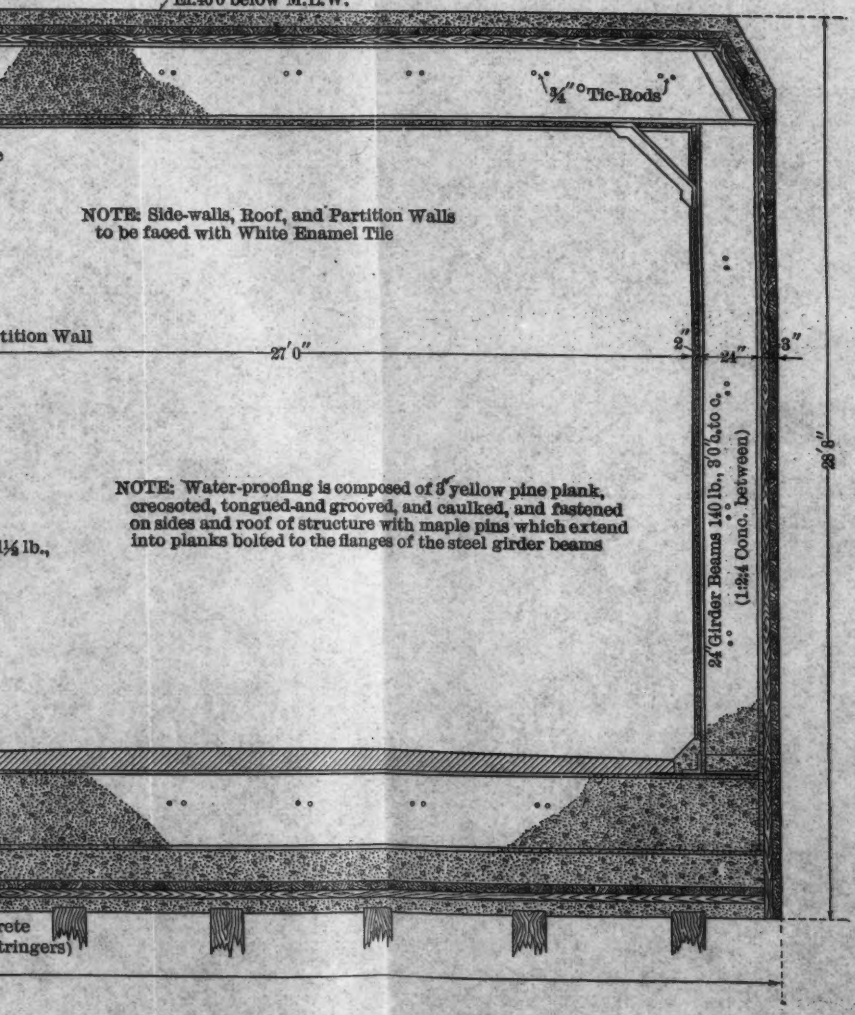
IN COMMEMORATION OF 100 YEARS PEACE BETWEEN UNITED STATES AND GREAT BRI



GREAT BRITAIN



was then pumped out, resulting in the completion of a pneumatic subaqueous working chamber, within which the "tunnel proper" was built.* Mr. McBean.

Mr. Kinnear states that in the fall of 1904, a committee was appointed to report on the feasibility of a tunnel under the Detroit River, at Detroit, and that the report was to include estimates of cost, etc. He states that the committee made the necessary investigations, reported favorably on the construction of a tunnel, and submitted estimates covering the different gradients for approaches, recommending a 2% grade west bound and a 1½% grade east bound. That the estimate as then prepared for the recommended tunnel was a good one, has been demonstrated by the actual cost of construction.

He likewise informs us that in July, 1905, the Committee was superseded by an Advisory Board of Engineers, and that the work of preparing plans was started in August, 1905, but he fails to mention the source of the Committee's data on which it based its estimate of the cost for the construction of the tunnel by the Subaqueous Working Chamber method, concerning which Mr. Hoff writes:

"effected a saving of about $2 000 000 over a shield-driven tunnel with compressed air, and to this should be added the capitalized saving in annual cost of operation on account of the tunnel being placed some 15 ft. higher, thus reducing by this amount the vertical lift of the tonnage passing through."†

Mr. Snyder's Fig. 27 is a cross-section of a roadway tunnel, which the writer prepared and submitted to the Hoboken Board of Trade. Since then he has prepared and submitted a design (Fig. 34) for a roadway tunnel under the Hudson River, on the proposed Canal Street Line, accompanied with a proposal to build the tunnel and its approaches for the sum of $5 500 000—just one-half the estimated cost of building a circular tunnel with roadways of the same width by the shield method. The writer has also prepared and submitted a design (Plate XXXIX) for a proposed highway tunnel under the Detroit River, at Detroit, Mich. The number of piles under the latter structure is greater than would be required ordinarily, except in places where the bottom of the river is filled in for the purpose of supporting the tunnel.

It was the writer's conception to build subaqueous tunnels, according to these designs, by constructing long sections of the tunnels in pontoons in which all the structural material would be put in place, except the concrete between the bottom girders inside of the sidewalls; bulkheading the ends of the sections; attaching either to the top or to the underside of the bottom girders a temporary water-tight floor; sinking the pontoon and removing it from under the struc-

* *Transactions*, Am. Soc. C. E., Vol. LXXIV, pp. 303, 328, 362.
† *Ibid.*, p. 371.

Mr. McBean.

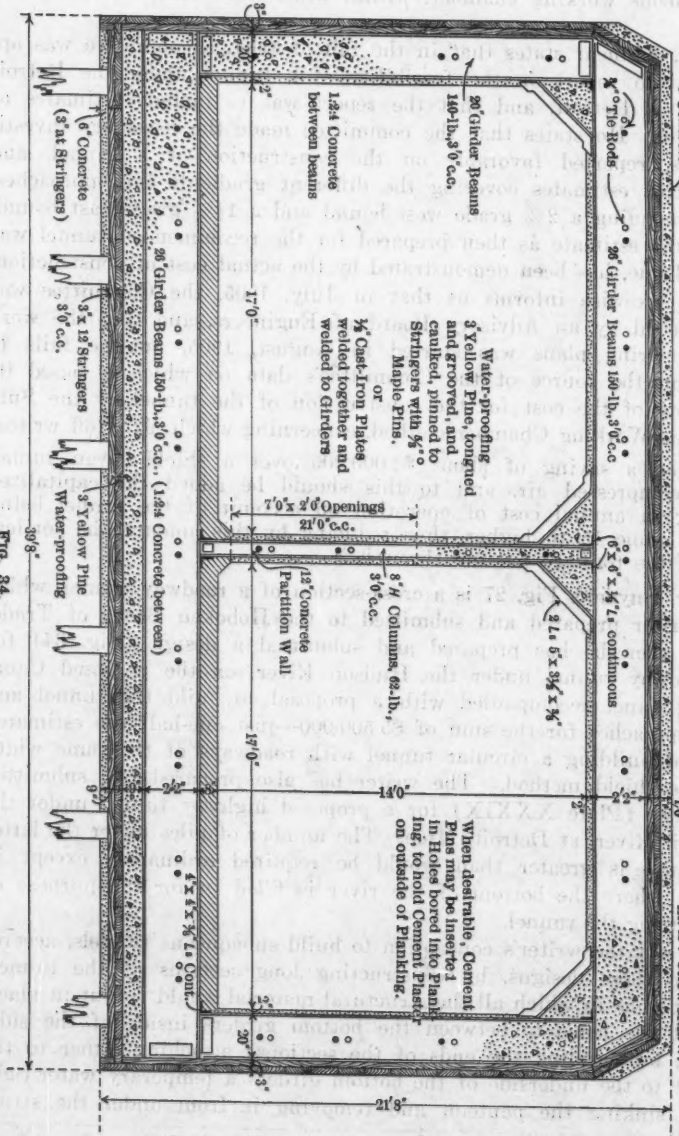


FIG. 34.

ture; overcoming the buoyancy of the structure by placing within it on its temporary floor a part of the material required for the bottom concrete; then lowering the structure on a temporary foundation of piles, driven into the bottom of the dredged trench, and cut off and capped at the proper depth to support some of the bottom girders; admitting a pressure of air, equal to the hydrostatic pressure at the level of the temporary floor; and then removing the temporary floor. The structure so constructed would then form a working chamber. The foundation would then be cleaned out, the foundation concrete, water-proofed with planking, would be put in place in air, and the section of tunnel completed. Mr. McBean.

The rectangular form of these designs, together with the water-proofing of creosoted, tongued-and-grooved, yellow pine planking, pinned on the outside of the structural material, renders them simple, durable, and economical for future subaqueous tunnel construction.

THE STEREOSCOPIC METHOD OF SURVEYING, AND A FIRST TRIAL OF ITS APPLICATION TO A RAILWAY SURVEY IN CHINA.

Discussion.*

BY F. LAVIS, M. AM. SOC. C. E.

Mr. Lavis.

F. LAVIS,† M. AM. SOC. C. E. (by letter).—This description of the application of the methods of stereoscopic surveying to railroad location is interesting from a theoretical standpoint, but there is little in the paper to show its value commercially, that is, to show that the necessary information for the location of the best line for the purpose of railroad construction through this valley was obtained by this method, at less cost than would have been possible by ordinary methods. As a matter of fact, cost is hardly mentioned except to note that one of the desirable minor instrumental aids costs about $6 000.

Apparently 10 men (engineers or engineering students) consumed most of 2 months in the necessary field work covering from 4 to 6 miles of line, though this is not quite clearly stated; if so, it hardly seems as if this method would compare favorably with those ordinarily used, namely, the typical American method, or the stadia method more generally used by European engineers.

There seems to be little in the paper to indicate the final degree of accuracy obtained. Speaking generally, it would seem that a map on a scale of 1:2 500, or approximately 200 ft. to the inch, which is virtually an enlargement from a very much smaller scale photograph, would have a rather large probability of error. As the matter stands,

* This discussion (of the paper by Georg A. G. Müller, Esq., published in August, 1914, *Proceedings*, but not presented at any meeting), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

† New York City.

Mr. Lavis.

it would almost seem as if the topographical map produced by this method was of approximately the same value as the topographical sheets issued by the United States Geological Survey on a scale of 1:62 500, which are excellent for reconnaissance projections, but not for anything more detailed; perhaps, however, a further explanation by the author may throw more light on this. Of course, assuming adequate results, the true test of any survey method for the location of a railway line is the cost of the final line staked out on the ground. It must always be kept in mind that the ultimate purpose of a railroad location survey is not the making of a topographical survey or the production of a topographical map, but the location on the ground of the best line the country affords under certain given conditions, and incidentally doing the work by methods which involve the least cost. The production of a topographical map, if this is necessary or even desirable, as it almost always is, is merely incidental to the final purpose, and its extent and accuracy should be governed solely by its use for the ultimate purpose in view.

It seems to the writer that, even disregarding the first cost of the very expensive outfit, and assuming that the stereoscopic method might enable one versed in its use to produce at a reasonable cost a topographical map having the necessary degree of accuracy to enable a line to be properly projected on it, the cost of actually reproducing this line on the ground would be considerably more by this process than by the usual American methods.*

It may be thought that, in using the stereoscopic method, the relation of the projected line to the triangulation points might be determined from the map and the line staked out from this, but this seems to the writer to be likely to produce results very much inferior to those obtained from the reproduction of a line quite close to a previously staked-out preliminary, inasmuch as the work involved in detailed adjustment of the line to the ground in such very rough country would be greatly increased. If the author can give any further information in regard to the final application of this method to the production of a railway line staked out on the ground, rather than the production of a topographical map, which is, of course, all this paper now does, it would be of considerable interest and add greatly to our ability to estimate the value of the new method, and judge of its practicability.

A METHOD OF DETERMINING STORM-WATER RUN-OFF.

Discussion.*

By Messrs. W. W. Horner, Charles W. Sherman, Robert E. Horton, and C. E. Grunsky.

Mr. Horner.

W. W. Horner,† Assoc. M. Am. Soc. C. E. (by letter).—The author presents a formula for storm-water run-off and introduces it as "empirical." He speaks of the "so-called rational method" and of the "formula method", and states "that the proposed formula gives results in all cases reasonably close to those which will be obtained by the rational method, and that the formula can be taken as an acceptable equivalent." Elsewhere, he speaks of the rational method as involving "cut-and-try methods" and as being "relatively laborious."

The author does not include in his paper any information in regard to the development or construction of his formula. The writer became interested in the manner of appearance of the variables in the new formula, and found that, for an ideal condition of area and slope, and with the type of rainfall curve which the author uses in comparing gaugings, he was able to derive from the theory of the "rational method" a formula very similar to that of the author. For this reason, the writer is of the opinion that the new formula should be described as a rational formula for ideal conditions.

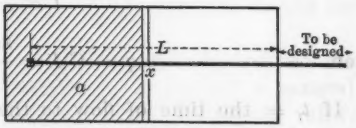

Fig. 5.

The derivation mentioned is of considerable interest, and is presented as follows: Assume conditions as shown in Fig. 5. A circular sewer having a grade of S feet per thousand, a length, L, and a drainage area at the lower end of A. Let a equal the area drained

* Continued from October, 1914, *Proceedings*.

† St. Louis, Mo.

Mr. Horner.

at any point, x, the sewer to be uniformly proportioned to carry the run-off at all points, and the tributary area to be proportional to the length; then the run-off at x will be

$$Q_x = a\,I\,c = 4\,r^2\,B\sqrt{r\,\frac{S}{1\,000}},$$

where r is the hydraulic radius at that point, and B is the coefficient of the Chezy formula.

Eliminating r from these two gives

$$V_x = \frac{B^{\frac{4}{5}}\,S^{\frac{2}{5}}}{26.4}\,(a\,I\,c)^{\frac{1}{5}}.$$

The time of flow may be expressed from

$$d\,t = \frac{d\,(L)}{V_x},$$

or, where

$$\frac{d\,(L)}{d\,(a)} = \frac{L}{A},$$

$$d\,t = \frac{L}{A\,V_x}\,d\,(a).$$

Substituting V_x from above, integrating between $a = 0$ and $a = A$, and dividing by 60 to reduce to minutes:

$$t_L = \frac{0.55\,L}{(C\,I)^{\frac{1}{5}}\,B^{\frac{4}{5}}\,\sqrt[5]{S^2\,A}} = \frac{0.55\,L}{q^{\frac{1}{5}}\,B^{\frac{4}{5}}\sqrt[5]{S^2\,A}}$$

assuming a rainfall curve of the form

$$I = \frac{90\,K}{t + 24},$$

then

$$q = C\,I = \frac{80\,K\,C}{t + 24}.$$

If t_l = the time of flow to the inlet and t the time through the sewer, then $t = t_l + t_L$, or

$$q = \frac{80\,K\,C}{t_l + t_L + 24}.$$

Substituting the value of t_L above and solving for q,

$$q + q^{\frac{4}{5}}\,\frac{L}{1.82\,(24 + t_l)\,B^{\frac{4}{5}}\,\sqrt[5]{S^2\,A}} = \frac{80\,K\,C}{24 + t_l}.$$

The velocity of flow to the inlet may be assumed to be proportional to the square root of the surface slope, or $V_l = x\sqrt{m}$.

If l = an average distance from the water-shed to the inlet, then

$$t_l = \frac{l}{x\sqrt{m}}.$$

Mr. Horner.

For average conditions, assume $l = 500$, $m = 10$, and $t = 5$.

Then $$\frac{l}{x} = 15.5, \text{ say } 16,$$

and $$t_l = \frac{16}{\sqrt{m}}.$$

Also, assume an average value of the Chezy coefficient, B, as 110; then the formula becomes

$$q + q^{\frac{4}{5}} \frac{L}{78 \sqrt[5]{S^2 A} \left(24 + \frac{16}{\sqrt{m}}\right)} = \frac{3.33 \sqrt{m}\ K\ C}{\sqrt{m} + 0.67}.$$

This formula, though based on several averages and assumptions, is a rational one; it differs slightly from the author's formula in the numerical coefficient and in the appearance of C under the radical with $S^2 A$. This appearance of C is irrational, and may warrant the use of the word empirical as describing the formula. The term, C, appearing as a one-fifth power, however, has little effect on the results, because, for a range of C from 0.3 to 0.8, $C^{\frac{1}{5}}$ varies only from 0.79 to 0.96.

If an average value of 0.9 were introduced into this formula, it would become

$$q + q^{\frac{4}{5}} \frac{L}{86 \sqrt[5]{C S^2 A} \left(24 + \frac{16}{\sqrt{m}}\right)} = \frac{3.33 \sqrt{m}\ K\ C}{\sqrt{m} + 0.67},$$

which is almost identical with that of the author. If other values of B, C, and t_l had been assumed, the numerical coefficients would not have agreed, but the manner of appearance of the variables would have been the same.

The writer wishes to ask why the coefficient, C, is called the ratio of "run-off to total rainfall"? The coefficient of run-off is generally considered as the ratio of the rate of run-off to the intensity of rainfall producing that rate. This latter definition has a definite meaning in sewer work, and the effect of changes in it are readily understood. The C, as defined by the author, is of importance in water-supply work, but does not appear to have any known relation to the rate of run-off.

Whatever the origin of the formula, it may be seen from the foregoing derivation that it may be expected to give reasonable results for certain average conditions. The conditions met in actual practice, however, will vary widely from any mean. In the main sewer of any large system, frequent changes of size and grade, of surface conditions, and even of soil conditions, will be encountered. By the rational method, all these items will enter in their proper place and be taken into account; in any formula, only a general mean condition can be considered, and, in any particular case, the results may vary widely.

Mr. Horner.

The writer is of the opinion that the formula will not give results in all cases reasonably close to those obtained by the rational procedure, and that in general it will not effect any economy of labor in design. In the new formula, all the data and the same analysis of them are required as for the rational method. For the purposes of design, a sewer is divided into a number of sections, according to the areas drained and the grades. In the rational procedure, the grade of a section enters into the calculation of the time of flow for the section, and has no relation to the grades of other sections; in applying the formula to each section, an average of all grades above is required. Again, the variable, m, in the rational method, affects only the initial inlet time, but in the formula it enters into each solution.

The writer has found the procedure of design by the rational method simple, direct, and comprehensible at every step. Although its application to a single unit of sewer in undeveloped territory may call for cut-and-try methods, in the design of a system of sewers, the procedure is definite, the design of each unit leading directly to the next. This is shown clearly in the tabulation for St. Louis conditions referred to by the author*.

The writer does not wish to discount the value of the new formula as a formula, for it is undoubtedly a great advance over the older ones cited in the paper, but wishes to emphasize his belief that the practice in sewer design has already advanced beyond the stage in which the whole problem may be solved satisfactorily by a single mathematical expression of any kind.

Mr. Sherman.

CHARLES W. SHERMAN,† M. AM. SOC. C. E.—The speaker agrees fully with Mr. Buerger's statement, "It is almost everywhere conceded that the rational system * * *, if used with proper discretion, will give very satisfactory results", but he is inclined to different views on many of the other statements in the paper. He believes that Mr. Buerger is mistaken as to the methods of determining storm-water run-off which are receiving most favor in the larger and better organized engineering departments, and he feels that, in presenting another empirical formula, unless it shall give results very closely paralleling those of the rational method (the possibility of which the speaker doubts), he is tending to foster a method of design which is irrational.

The author suggests as one of the reasons that, in his opinion, an empirical formula is likely to be more popular in such design than the direct application of the rational method, that the latter is relatively laborious, and "requires, in addition, a material exercise of judgment." With regard to the comparison of the labor required in the solution of the true rational method and the use of the suggested

* *Engineering News*, 1910, Vol. 64, p. 326.

† Boston, Mass.

Mr. Sherman.

formula, it is evident that the same preliminary work of determining drainage areas, laying out sewer lines, estimating grades, etc., must be done, in any event; and an examination of the diagrams presented with the paper indicates at least a possibility that finding a value of P by following out four lines in one complex diagram, and a value of N by similarly following five lines in another and more complex diagram, and finally, by determining the location of these two values on a third diagram, to obtain the required run-off figure, would be very nearly as laborious as the direct solution of the rational method, besides being accompanied with a greater likelihood of error caused by misreading the diagrams. Disregarding this point, however, does the author wish us to believe that an engineer, not sufficiently familiar with the territory under consideration and with methods of design to be trusted to exercise his judgment in the use of the rational method, can proceed to design storm-water sewers by the use of the proposed formula and diagrams? The speaker is of the opinion that no one without ample understanding of the subject should be entrusted with matters of such importance, and that putting a formula or diagrams in the hands of inexperienced or untrained men and leaving them to obtain results by substitution of values is not to be commended.

Although the author does not claim definitely that the comparison of his formula with the older empirical formulas, such as that of McMath, has any bearing on the adequacy of a method which is intended to give figures closely paralleling those of the rational method, he submits such comparisons in such a way as to lead to their use as a gauge of his formula. The speaker does not think that this comparison should be taken as significant, and, accordingly, he feels that the presentation of the older empirical formulas is out of place in this paper. He would call attention to the fact, however, that the Hering formula, representing the New York diagrams, as quoted in the paper (presumably from the paper* by Charles E. Gregory, Assoc. M. Am. Soc. C. E.), differs from the formula as first written by Mr. Hering, in the Report of the Baltimore Sewerage Commission, 1897, in that the exponent of A is written 0.167, whereas, as given by Mr. Hering, this exponent is 0.15. Although this difference seems slight, a comparison of results obtained by using the two forms of the formula shows that they may differ as much as 15% for large areas.

The author quotes the fact that in storm-sewer design in several large cities, widely different values of R (representing the rate of rainfall) have been used, as an indication that the earlier empirical formulas have been improperly applied. His criticism would seem to imply that R in these formulas was intended to represent the rate of rainfall for a storm of some particular duration. As a matter of fact, however, the use of $R = 4$, in one locality, and $R = 1$, in

* *Transactions*, Am. Soc. C. E., Vol. LVIII, p. 458.

Mr. Sherman.

another, merely means that, whereas the latter designer has assumed that the critical storm for which he must make provision is one lasting an hour or more, the former has assumed a condition in which a storm lasting perhaps from 10 to 20 min. will give him the most serious conditions.

If, as Mr. Buerger says, in the application of the older formulas, "it is likely that, for a mountainous, rocky district of small size, the same constants may be used as for a flat beach town of large extent", what is to prevent a similar misuse of constants in his proposed formula?

Mr. Buerger's statement, "that formula methods are much more popular", may be true if tested by the number of individual engineers using one method or the other. On this point the speaker has no information, but he is of the opinion that present practice in the engineering departments of the larger American cities, and some of the smaller ones where considerable attention has been paid to this subject, is distinctly in favor of the use of the rational method. Inquiry of the officials of seventeen such places has shown that ten of them use the rational method or some of its modifications, two use the McMath, three the Bürkli-Ziegler, and two the Hering formula. The places referred to are as follows:

Mr. Sherman.

The speaker also differs with Mr. Buerger's apparent assumption that the results obtained by the application of his formula may be fairly tested by comparison with the results of such sewer gaugings of storm flow as are available, because by far the greater number of these gaugings have been made when the storms were of much less magnitude than those on which design must be based. It must also be borne in mind that in design it is of the first importance that the designer form a reasonable judgment of the future condition of the district under consideration, and adopt his coefficients and constants so that the drains may be adequate when the district has developed, rather than at the present moment, except in the rare case of the district which is already fully developed. It appears, however, that in the comparisons made by the author, his formula gave figures less than the actual gaugings in a large percentage of the cases. It appears, also, that, in making his comparisons, he has omitted many reported gaugings. The Report of the Committee of the Boston Society of Civil Engineers, on Run-Off from Sewered Areas*, contains figures for many more gaugings than those quoted by Mr. Buerger.

In discussing the rational method, the author states that the most complete and satisfactory treatment of it is that given by Mr. August Frühling. Mr. Frühling's analysis is unquestionably complete, and should be studied carefully by every sewer designer. In the speaker's opinion, however, the treatment of the problem given by him is needlessly complex. According to Frühling's analysis, the coefficient, C, in the rational formula, $Q = C\ I\ A$, is made up of three parts: first, a coefficient of rainfall distribution; second, a coefficient of retardation due to the fact that under ordinary conditions all portions of the drainage area are not contributing water at the same rate; and third, a coefficient of retention or of imperviousness, depending mainly on the porosity and roughness of the surface. A clear conception of the effect of these various factors is of the greatest importance in studying the results of gaugings, particularly as many such gaugings have been made when the duration of the heavy rain has been less than the time of concentration of the drainage area, so that the coefficient of retardation is an important factor. In design, however, it seems to the speaker that the most severe conditions must be assumed, in which case the coefficients of rainfall distribution and of retardation are unity, and the run-off coefficient is equal to the coefficient of imperviousness.

The proposed formula seems to be open to serious criticism as to the method in which the rainfall factor is introduced. Mr. Buerger apparently implies that records of intense storms, lasting 60 min., may often be obtained when trustworthy records of intensity of precipitation for shorter periods are not to be had. As a matter

Journal, Boston Soc. Civ. Engrs., June, 1914.

Mr. Sherman.

of fact, the reverse is more likely to be the case. Intense storms of short duration are much more frequent than those of longer duration, and in case the rainfall record covers but a limited period, it is much more probable that it includes figures approximating maximum or critical conditions for periods of less than ½ hour than for longer periods. It is extremely unsafe, therefore, to infer from any limited record of rainfalls for periods of 1 hour what the intensity of precipitation may be which should govern storm-sewer design.

Even were it possible to determine readily what rate of precipitation for a period of 60 min. is to be expected or assumed as the critical rate, for the purposes of design, it would still be improper to assume that the intensity for any other period of time bears some definite ratio to that for 60 min., as seems to be the case in the proposed formula. The only statement in the paper relative to this ratio, which the speaker has been able to discover, is that at the foot of page 1742,* where it is assumed that "$I = \frac{80\,K}{20 + t}$", or, in other terms, $\frac{I}{K} = \frac{80}{20 + t}$. This relation holds true only for a rainfall curve of the form $I = \frac{A}{20 + t}$. Although this curve has been assumed by some designers as representing approximately rainfall conditions in the Eastern Atlantic States, others have derived altogether different curves, and this form would not be at all applicable to some other parts of the country.

The speaker has had occasion recently to study rainfall records in a number of the more important cities throughout the United States, and to bring together rainfall curves suggested by various engineers for different localities. Though the form indicated by the formula, $I = \frac{A}{B + t}$, is popular with a large number of engineers, for some localities values of B widely differing from 20 have been found necessary to fit the conditions discovered, and other engineers have used formulas of the exponential type, represented by the equation, $I = \frac{D}{t^x}$, or even more complex forms of expression.

Fig. 6 shows a series of curves representing the ratios between the intensity of precipitation for any period and the precipitation for a period of 60 min. The full line represents the curve assumed by Mr. Buerger, $\frac{I}{K} = \frac{A}{20 + t}$. The other curves represent the ratios which would be obtained from rainfall curves proposed by several engineers for various localities. It is seen that, although Mr. Buerger's curve

* *Proceedings*, Am. Soc. C. E., for August, 1914.

follows, in general, near the median line, the variations are very considerable, so that, if the rainfall curves presented for the other localities are even approximately correct, material errors might be introduced by the use of the equation adopted by Mr. Buerger. Mr. Sherman.

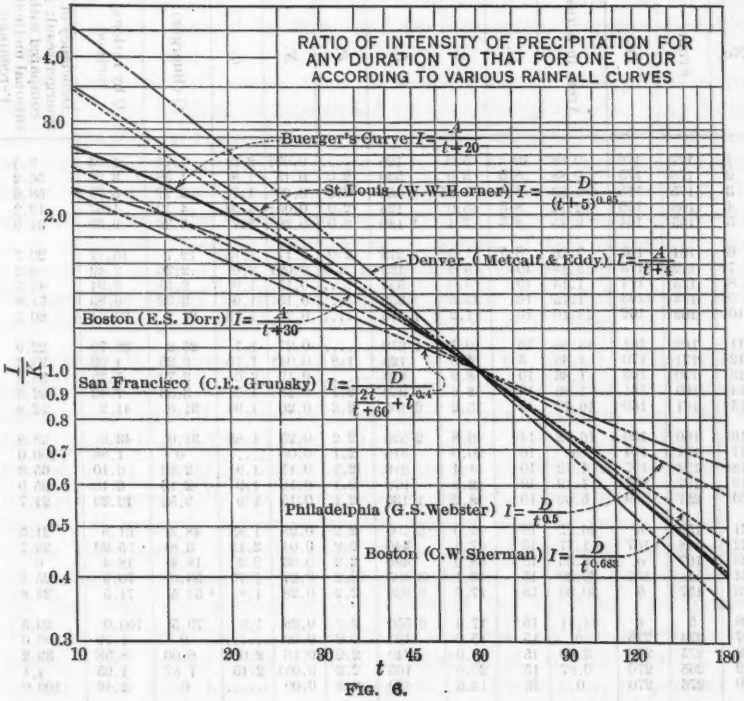

FIG. 6.

After all, however, the crucial test of the proposed method, as stated by Mr. Buerger, is the accuracy with which it reproduces the results to be obtained by the direct application of the rational method. The speaker has carried such a test farther than Mr. Buerger has done in his paper by applying it in detail to each step of the problem* presented by W. W. Horner,† Assoc. M. Am. Soc. C. E., with the results given in Table 16.

From Table 16 it is at once apparent that only in one case of the forty-two computations tabulated does the result obtained by Mr. Buerger's method agree with that computed by the rational method. In every other case Mr. Buerger's method gives a less result, and usually a considerably less result. In five cases the Buerger method

shows a deficiency of 100%, or indicates that there would be no flow, whereas the rational method indicates an appreciable quantity of water to care for. These cases are at the upper ends of the sewers, where there is no drainage area tributary to the street inlets, but where allowance is made in the rational method for the probability

of roof-water drains being connected with the sewers. In such a case, the formula method necessarily fails, and it is necessary to apply judgment, that is to say, the rational method. Neglecting the cases where the deficiency as tabulated is 100%, the deficiency in the quantities computed by Mr. Buerger's, as compared with the rational method, ranges from 0 to 65%, and by inspection averages probably at least 25 per cent. Mr. Sherman.

It is possible, of course, that the speaker has misinterpreted some portion of the method recommended by Mr. Buerger, or he may have made mistakes in reading from the complex and small-scale diagrams accompanying the paper. He can only say that he has studied the paper carefully and endeavored to apply the method correctly, in accordance with the description, and to read the diagrams as closely as is ordinarily feasible in handling diagrams of this character. As a result of this test, the speaker is forced to the conclusion that Mr. Buerger has failed in his attempt to obtain a formula which will give results approximating those of the rational method.

ROBERT E. HORTON,* M. AM. SOC. C. E. by letter).—The writer agrees with Mr. Buerger that the McMath, Bürkli-Ziegler, and similar storm-water run-off formulas have been given practical application far beyond justifiable limits. On the other hand, he is not convinced, from anything which appears in the paper, that the Buerger formula is essentially an improvement, or that the Engineering Profession, if properly informed on the subject, does or would prefer to use a complicated formula such as the author presents, rather than the so-called rational method. This statement is based principally on the fact that the method of derivation of the formula, the specific data, or the assumptions on which it is based, are not given in the paper. The writer feels obliged to state that, in his opinion, the author is in duty bound, in fairness to the Profession, to present in full the derivation of his formula, if he expects it to be adopted generally. Mr. Horton.

In reference to this the writer feels justified in asking for an explanation of the necessity for the use of so complex and awkward a formula—a veritable *cheval de frise,* in fact. The formula contains some sixteen terms, and, if it was capable of direct solution, would require at least an equal number of mathematical operations, but it is not only an implicit formula incapable of direct solution, but even when the necessary factors (P and N) are given, it is only capable of solution by the use of a complicated diagram or by process of trial and error. The writer hesitates to accept the proposition that engineers would prefer to work out the run-off from a system of diagrams requiring such complicated operations as are necessary even

* Albany, N. Y.

Mr. Horton.

for the graphical solution of this formula, rather than use the rational run-off method in which direct calculations can be applied.

The formula, it appears, involves only six factors: the length of the sewer, the run-off ratio, the tributary area, the slope of the sewer, the slope of the ground surface, and the rainfall rate. After all, the most important elements governing the results are left to judgment, as in the case of the older formulas; and, furthermore, it is difficult to see just why so thorny and centipedal an expression is necessary to express the relations between these elements. In the hope that the formula is really as good and useful as its author apparently believes it to be, the writer feels amply justified in calling for full explanation of the assumptions on which it is based and the method of its derivation, and, furthermore, for the presentation of adequate reasons for the use of so complicated an expression.

The case is by no means parallel to that of the use of the Kutter formula. The latter is in reality a much simpler expression, although so complicated that its direct solution is seldom undertaken, but it did not profit by its complexity. As a matter of fact, it seems to have been well established that the original and simpler formula, derived without taking into account the Mississippi River experiments—later proved to have been erroneous—would have been far better; but, assuming, as is no doubt the case, that the only use of either formula would generally be through the medium of graphical solution, the Kutter formula can be solved by a single operation, with Roe's diagram, and by only two operations, with Kennison's diagram. The solution of the Buerger formula, on the other hand, requires ten operations on three diagrams. Undoubtedly, these diagrams, if on a large enough scale, could be read with accuracy, but their use seems to the writer to be very tedious and the result somewhat uncertain on account of the danger of accumulated error in reading from one intersection point to another, where there are several operations to be performed on the same diagram.

Mr. Grunsky.

C. E. GRUNSKY,* M. AM. SOC. C. E. (by letter).—As the result of an interesting analysis of available run-off data, the author has worked out an approximation formula which may turn out to be better than the older formulas of a similar nature, such as those by Bürkli-Ziegler and McMath.

In this new formula, however, as in all others for the determination of the maximum run-off, the element of greatest uncertainty is the factor based on the relative imperviousness of the surface of the water-shed. This being the case, and all approximations of this factor being largely dependent on the judgment of the engineer, the question arises: Why should it seem necessary to substitute a complicated

*San Francisco, Cal.

formula for such simple expressions, having a rational and theoretic basis, as those presented by the writer in his paper on "The Sewer System of San Francisco and a Solution of the Storm-Water Flow Problem"?* Mr. Grunsky.

Using Mr. Buerger's notation,

$$q = \frac{4.36\,C\,K}{\frac{2\,t}{t+60} + t^{0.4}},$$

is the formula for the maximum run-off, in cubic feet per second per acre, if the San Francisco type of limiting rain intensity curve is adopted, and

$$q = \frac{5\,C\,K}{\sqrt{t}},$$

in case the parabolic form of limiting curve is preferred.

For comparison, results computed by these formulas, and containing the same elements as those used by the author, are presented in Table 17, which is the author's Table 13, with two new columns added.

TABLE 17.—COMPARISON OF VARIOUS FORMULAS FOR STORM-WATER FLOW.

The critical time, t, in the absence of any information relating to the shape of the water-sheds, was determined from the length of the conduits as assumed by the author and from velocities of concentration, ranging from 3 ft. per sec. in the smallest areas to 6 ft.

* *Transactions*, Am. Soc. C. E., Vol. LXV, p. 294.

Mr. Grunsky,

per sec. in the largest ones, noted in the table. To this 5 min. were added for the time required to reach the sewer inlets. It was assumed that the critical time, t, would be about two-thirds of that required for water to flow to the gauging point from the most remote parts of each area. This method of approximating the critical time is not advocated as being a satisfactory one, but is here adopted merely to obtain relatively consistent results for comparison with those obtained by other formulas.

The successful application of the formulas suggested by the writer depends on two things: First, the determination of the limiting rain curve for the region under consideration; and second, the approximation of a value for t. Neither of these presents any serious difficulty, one being readily deduced from rain records and the other from the topographic features of the area for which maximum discharge is to be estimated. It is not believed that the type of formula for maximum run-off which these older formulas represent, can be materially improved.

The author accepts for rain intensity the formula:

$$I = \frac{80\,K}{20 + t},$$

this being of the type which has found acceptance by many engineers in the East.

The writer, on the other hand, has suggested

$$I = \frac{C}{\frac{2\,t}{t + 60} + t^{0.4}},$$

or

$$I = \frac{C_1}{\sqrt{t}},$$

where C and C_1 are constants to be determined for any locality from the rain records.

The eastern type of formula has the defect that it cannot be used for large values of t, etc. To illustrate this fact, the following comparison is made:

For $K = 1.00$ in., the eastern formula, as adopted by the author, would make

$$I = \frac{80}{20 + t}.$$

The writer's San Francisco formula would make

$$I = \frac{6.14}{\frac{2\,t}{t + 60} + t^{0.4}}.$$

Mr. Grunsky.

The writer's parabolic formula would make

$$I = \frac{7.75}{\sqrt{t}}.$$

The quantity of rain in t minutes, according to these several formulas, would be, for the special case of $K = 1.00$:

By the author's eastern formula..... $\dfrac{1.33\ t}{20 + t}$.

By the writer's San Francisco formula..... $\dfrac{t}{60}\left(\dfrac{6.14}{\dfrac{2\ t}{t + 60} + t^{0.4}}\right)$.

By the writer's parabolic formula..... $\dfrac{\sqrt{t}}{7.75}$.

120	0.57	0.75	0.71	1.14	1.50	1.41
240	0.31	0.63	0.50	1.23	2.52	2.00
600	0.13	0.42	0.32	1.29	4.20	3.16
1 440	0.055	0.30	0.20	1.32	7.20	4.90

Table 18 gives a comparison of the rain intensities and quantities of rain, as determined by these expressions. It will be noticed that, although there is a sufficiently close agreement between them for time periods of less than 1 hour—at which point, on the assumption of $K = 1.00$, they are made to agree—the departure of the results by the eastern formula from those obtained by the formulas recommended by the writer becomes very marked when the value of t is materially greater than 60 min. The constants for the writer's formulas can be determined when the maximum quantity of rain for any time period up to 24 hours, or even longer, is known. This is not the case for the eastern type of intensity formula, the use of which, for this reason, should be discouraged.

Mr. Grunsky.

A mere inspection of Table 18 will show that the quantities of rain computed by the formulas, $I = \frac{80}{20+t}$ and $I = \frac{1.33\ t}{20+t}$, fall far short of what is known to be the fact. In any locality in which the rainfall in 1 hour is 1.00 in., the greatest possible rainfall in a day will certainly exceed 1.32 in.

Either of the two formulas for rain intensity suggested by the writer* is good for low values of t, and is also applicable to much longer periods of time than ordinarily come under consideration in urban or suburban run-off studies.

At Kansas City, Mo., during the night of September 6th and the morning of September 7th, 1914, the following quantities of rain fell:

Greatest quantity in	5	min	.....	0.64	in.
" " "	10	"	.....	1.01	"
" " "	15	"	.....	1.26	"
" " "	30	"	.....	1.56	"
" " "	1	hour	.....	1.97	"
" " "	2	hours	.....	2.78	"
" " "	5	"	.....	4.76	"
" " "	10	"	.....	6.94	"

Accepting for purposes of comparison the greatest recorded rainfall of this storm during 1 hour as the value of K, that is $K = 1.97$, then the additional comparison in Table 19 can be made, which again indicates the superiority of the writer's formula (of either the San Francisco or the parabola type) when the duration of the rain is materially greater than 1 hour.

TABLE 19.—COMPARISON OF THE RAINFALL AT KANSAS CITY, MO., WITH RESULTS BY FORMULAS.

Time, in minutes. (1)	For $K = 1.97$. Greatest Quantities of Rain, in Inches. Observed at Kansas City. (2)	Buerger. (3)	Grunsky, San Francisco $C = 12.1$. (4)	Grunsky, Parabola $C = 15.3$. (5)	Quantity of Rain. Grunsky, Parabola $C = 18.0$. (6)
5	0.64	0.53	0.50	0.57	0.67
10	1.01	0.88	0.72	0.80	0.95
15	1.26	1.13	0.90	0.98	1.16
30	1.56	1.58	1.32	1.39	1.64
60	1.97	1.97	1.97	1.97	2.33
120	2.78	2.26	2.98	2.78	3.29
300	4.76	2.46	5.28	4.40	5.20
600	6.94	2.54	8.23	6.22	7.35

* *Transactions*, Am. Soc. C. E., Vol. LXV, p. 422.

Mr. Grunsky.

It is probable that the actual limiting rain curve for Kansas City for low values of t will fall a little beyond either of the curves indicated by the figures in Columns 4 and 5. If the rainfall records of this September storm were to be made the guide in establishing a limiting curve for short time periods, the constants in the formulas, in other words, would be determined from the rainfall in 15 and 30 min. rather than from the fall in 60 min.

For a limiting rain intensity curve determined from such a single storm record as that in September, 1914, at Kansas City, the writer would recommend that C_1 be introduced into the parabolic formula at a value of 18. That is, for such a special case, there would be:

$$I = \frac{18}{\sqrt{t}}.$$

It may be added, in conclusion, that the simplicity of its form and close correspondence with the observed facts, both for short and for fairly long time periods, are elements in favor of the use of the parabolic type of limiting rain curve.

WATER SUPPLY OF THE SAN FRANCISCO-OAKLAND METROPOLITAN DISTRICT.

Discussion.*

By Messrs. F. T. Robson and L. J. Le Conte.

Mr. Robson.

F. T. Robson,† Assoc. M. Am. Soc. C. E. (by letter).—The author has mentioned briefly the water supply—as developed and as proposed—of the East Bay shore. Several statements are startling, to say the least, and although the facts as given may be appreciated by engineers who have made a special study of the matter, yet to the Profession at large, and particularly to the local public, the acute water situation of the cities of Alameda and Contra Costa Counties comes as a severe shock. The public has long known of the unsatisfactory financial condition of these water companies, but has not been so well informed as to the water supply.

Water Supply of the East Shore Region of San Francisco Bay.

San Francisco has dominated everything in Central California for such a long time that the possibility that she will soon be passed in population and industrial growth by the cities on the East Shore has not come to be realized very generally. The cities of the East Bay region have been content to let their sister city make the fight for water alone, expecting to share in the spoils when the fight was won. It appears, however, that it will be too late to wait until San Francisco has brought in mountain water; by that time the growth of the East Shore will have been much retarded. The seriousness of such a situation deserves more emphasis and detailed analysis

* This discussion (of the paper by H. T. Cory, M. Am. Soc. C. E., published in September, 1914, *Proceedings*, and presented at the meeting of November 4th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

† San Francisco, Cal.

Mr. Robson.

than that given by Mr. Cory in his paper, and it is felt that some additional facts may prove of interest.

In general, the present supply is a follows:

THE PEOPLES WATER COMPANY.

Historical.—As stated by Mr. Cory, the Peoples Water Company now supplying the greater part of the water used in the mainland cities, is the successor of nine lesser companies which have entered the field in the past forty-five years. Each supplied water to one or more of the transbay cities when they were much smaller than they are at present.

The consolidated plant does not constitute a well-designed and well-built water system. Although materials of an inferior grade were used extensively before consolidation, a big improvement has since been made. Of necessity, a number of features are obsolescent because of the rapid increase in population.

A very large part of the population lies below the 150-ft. contour, but the most desirable residence districts are on the foot-hill slopes to and beyond a 600-ft. elevation. Obviously, the water supply should be divided into at least three vertical zones with storage for each. In general, this has not been done, and could not be expected in a plant resulting from the consolidation of a number of disjointed systems, largely unrelated, and often duplicated through competition.

The main developments were as follows:

The Contra Costa Water Company was formed in 1866 to supply the small City of Oakland, and took water from Temescal Creek, later building the Temescal Reservoir.

Somewhat later the Sausal Water Company began supplying Brooklyn, a part of the present City of Oakland, with water from Sausal Creek.

The California Water Company began operations a little later to supply the Town of San Leandro, from San Leandro Creek, and began the construction of the San Leandro Dam. Both these companies were absorbed by the Contra Costa Water Company, which, in 1875, completed the San Leandro Reservoir (Lake Chabot).

The Alameda Artesian Water Company was formed to supply Alameda, then a small detached town. A group of pumped Artesian wells near Fitchburg was the source of supply. When the population reached 14 000 this became inadequate, and as the only additional supply then possible, because of cost, was the surplus water of the reorganized Contra Costa Water Company, the latter, in 1900, took over the Alameda Company.

The Piedmont Spring Water and Power Company—1892—furnished what is now Piedmont and part of Oakland with water from

Mr. Robson.

tunnels driven in the hills back of Piedmont, in Diamond Canyon, and another part of Oakland from wells in Oakland.

The Oakland Water Company, about 1893, was to supply a part of Oakland and the Town of Alvarado, by a pumping plant drawing on Artesian wells near Alvarado. Within a year it acquired the the Piedmont Spring Water and Power Company.

The East Shore Water Company was organized about 1898, by interests friendly to the Contra Costa Water Company, and soon after took over the Alameda Water Company. It supplied the higher parts of Berkeley and East Berkeley—then several miles north of Oakland—with water from Wildcat, Cordonices, and Wilson Creeks, from Summit and Berryman Tunnels, and from Pfeiffer Springs. When these sources proved inadequate, the only available increase within the limits of available capital was a surplus of the Contra Costa Water Company, and, therefore, the latter company soon took over the East Shore Water Company.

Prior to the advent of the Piedmont Spring Water and Power Company, in 1892, the Contra Costa Water Company, by acquiring the Sausal and California Water Companies, was in exclusive possession of the field. In November, 1894, the Oakland Water Company (which had acquired the Piedmont Spring and Water Company) first supplied Oakland with water. For the next five years competition was severe and wasteful—the Oakland Water Company paralleling more than 100 miles of the Contra Costa Water Company's mains in Oakland, the only territory invaded. In 1899 these competing companies consolidated, the Contra Costa Water Company continuing the business.

Thus, by the end of 1899, the Contra Costa Water Company had, willingly and unwillingly, acquired and merged seven water companies.

The Pinole Water Company was formed in 1905 to take water from the Pinole Creek water-shed and supply a part of the Contra Costa Water Company's territory, the surplus of the latter Company's supply having been exhausted by the greatly increased demand. In a few months, it was purchased and merged—before any works were completed.

In 1906 the Syndicate Water Company was formed by the financial interests behind the Realty Syndicate, which, in 1904, started acquiring and developing on an immense scale the wonderfully attractive foot-hill suburban property on the East Bay side. One part of its programme resulted in the building of the Key Route Ferry and suburban electric railway system, now carrying more than 14 000 000 passengers annually. The deficient and unsatisfactory water supply of Oakland and Berkeley threatened the success of the Syndicate's plans. Rights and holdings were acquired on San Pablo and San Leandro Creeks, and construction was begun to develop enough water

Mr. Robson.

to afford—with that of the Contra Costa Water Company—a supply for several years. After some negotiations, the new interests took over the old company and merged under the name of the Peoples Water Company on January 1st, 1907. At that time there were 28 000 connections, mostly unmetered, and 18 000 000 gal. per day were supplied. At present, this corporation has about 60 400 taps, 99% of which are metered; yet the consumption has been kept at about the same quantity as it was 7 years ago. Formerly, a wholesale rate was made to industrial plants and large consumers, but, when the consumption had almost reached the limit of the supply, wholesale rates were discontinued, with the result that many private wells were sunk where there was the slightest chance of securing water. The high price of water has had a bad effect on industrial growth.

Essential Engineering Features.—Fifteen sources of water supply, comprising four surface-water and eleven ground-water sources, have been used during the past 10 years by the Peoples Water Company and its predecessors, as shown on the map, Fig. 24. For the use of this map, and also the profile, Fig. 25, containing data regarding these sources of supply, the writer is indebted to the courtesy of J. H. Dockweiler, M. Am. Soc. C. E.

Lake Chabot, also called San Leandro Lake or San Leandro Reservoir, with a water-shed of 41 sq. miles, was created by an earthen dam, 125 ft. high, across San Leandro Creek. The elevation of the top of the dam is 242 ft. above sea level, and, as reduced by silting, the reservoir now has a capacity of 4 840 000 000 gal., or 14 858 acre-ft. Water flows from the reservoir to a battery of Hyatt mechanical filters, then to a clean-water basin, and thence by gravity to the 38½-in. riveted steel main leading to Oakland and connecting on East 14th Street, near High Street, with the main from the Alvarado and Fitchburg wells. There, the three waters are mingled and subsequently picked up at the 24th Avenue pumping station for distribution. The dam built in 1875 was raised 10 ft. in 1892, and the flow line now contains 447 acres. In the past 10 years, the draft has varied from a maximum of 3 698 000 000 gal. during 1907, to a minimum of 2 152 000 000 gal. during 1911. The safe and dependable draft is presumed to be 6 000 000 gal. per day.

Temescal Reservoir, about 4½ miles northwest of the Oakland City Hall, has a capacity of 150 000 000 gal., or 460 acre-ft., and the flow line includes 16.75 acres. It is created by an earthen dam, 40 ft. high, across Temescal Creek, has 3½ sq. miles of water-shed, and a flow-line elevation of 436 ft. Water is carried by a 16-in. riveted steel pipe through five mechanical filters (one Hyatt and four Loomis) to a clean-water reservoir, with a capacity of 750 000 gal., at an elevation of 375 ft. Thence it is sent to Berkeley and Oakland by gravity. The draft from this source varies from a maximum of

Mr. Robson.

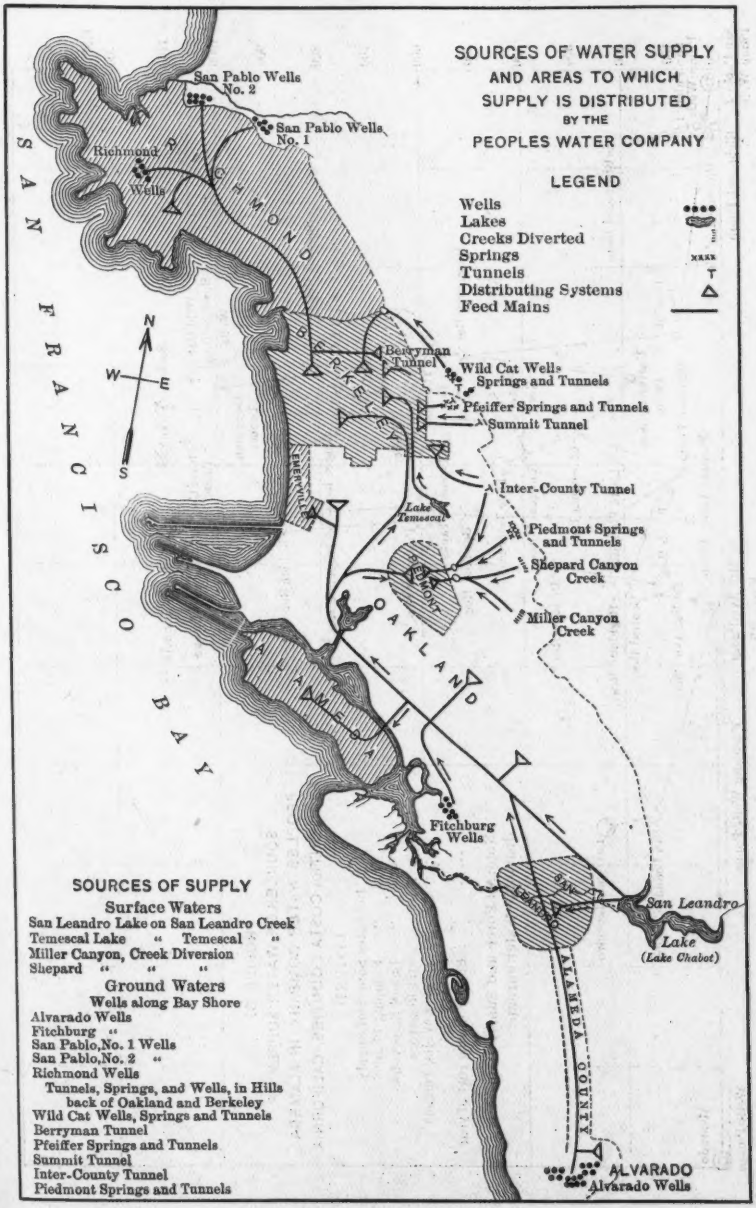

FIG. 24.

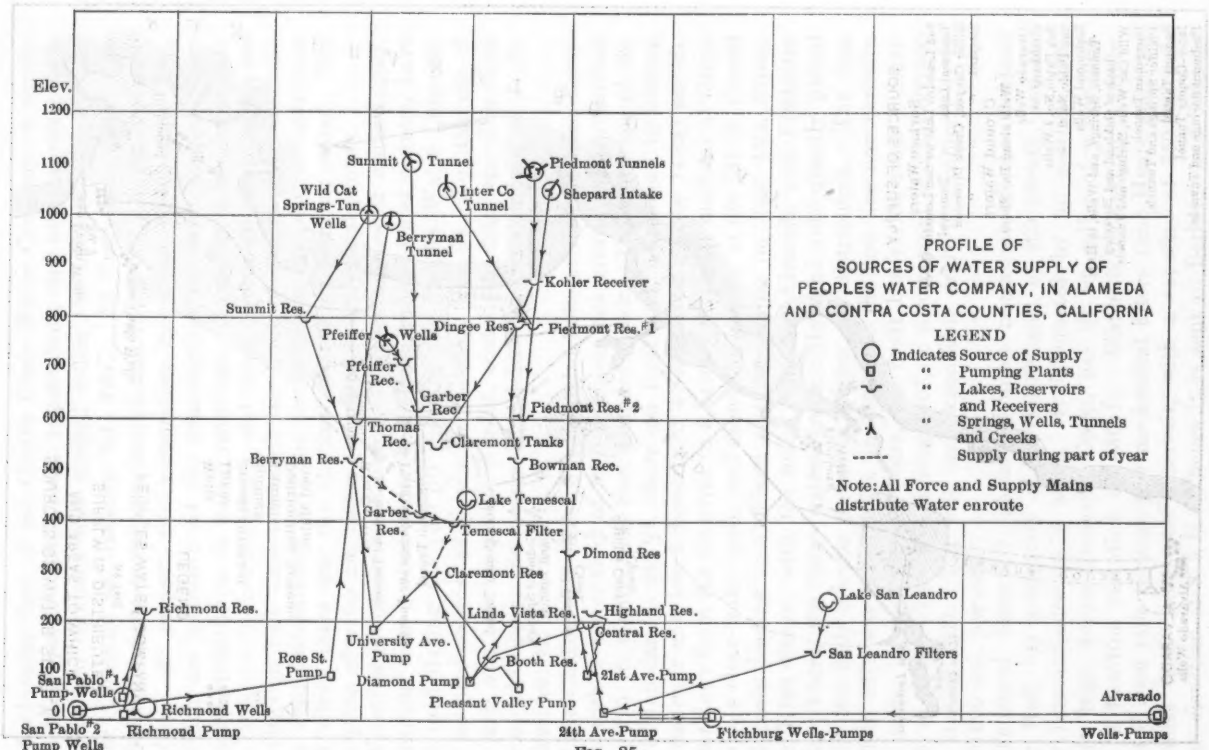

FIG. 25.

Mr. Robson.

206 500 000 gal., in 1906, to a minimum of 126 000 000 gal. in 1904. The safe and dependable draft is said to be 400 000 gal. per day. Mr. Robson.

Shephard Canyon waters are diverted from the north fork of Sausal Creek, in Shephard Canyon, by a small wooden dam, and through a 7-in. riveted steel pipe leading into Piedmont Reservoir No. 1. Thence it is conducted to Piedmont Reservoirs Nos. 2 and 3, and supplies the higher levels of Piedmont. The draft has varied from a maximum of 32 000 000 gal., in 1907, to 25 000 000 gal., in 1910.

The Miller Creek Canyon water is diverted from the east fork of Sausal Creek, and conveyed by a 2-in. pipe to connect with a 7-in. pipe leading from the Shephard Canyon source to Piedmont Reservoir No. 1.

The ground-water supplies consist of about 150 wells strung along the east shore of the Bay in five localities, from Alvarado to north of Richmond. At present these supplies are being drawn on for about 12 000 000 gal. per day, of which 85% comes from about 35 wells near Alvarado. From tunnels, wells, and springs in the hills back of Oakland and Berkeley—five sets—about one-tenth as much water is obtained as from underground sources along the Bay Shore, say, 1 000 000 gal. per day, of which about one-half is from Wildcat wells and tunnels. These ground-water supplies are not filtered.

In addition to the four impounding reservoirs, Lake Chabot, Temescal, and Piedmont Nos. 1 and 2 (which have a combined capacity of 5 011 000 000 gal., or 15 384 acre-ft.), there are thirteen distributing reservoirs with capacities of from 158 000 000 to 28 000 gal. (total 240 000 000 gal.), and at elevations of from 80 to 950 ft.

There are five primary and six "booster" pumping stations, with capacities of 16 500 000 and 35 600 000 gal. per day, respectively, with 10 000 000 and 20 000 000 gal. as a daily average. Of the total pumpage about 48% is pumped once, 33% twice, 18% three times, and 1½% four times.

As has been said, the distribution system has about 800 miles of pipe, of which about 48% is 2-in. and less, and 50% 4-in. and less; 35% is cast iron, from 3 to 16-in.; 10% iron and steel, riveted, from 4 to 37-in.; 50% standard screw, from ⅛-in. to 8-in.; and the remainder, converse, cement-lined casing and tubing.

Union Water Company of California.

The Union Water Company is the next in importance serving those communities directly across the Bay from San Francisco. It resulted from the activities of the Bay Cities Water Company formed in 1902 to supply water to all the Bay cities.

Historical.—When, in 1901, C. E. Grunsky, M. Am. Soc. C. E., then City Engineer of San Francisco, first reported on a Sierra water supply of 60 000 000 gal. per day, many engineers believed such a

Mr. Robson.

quantity of water could be obtained more cheaply from near-by sources. This fact and the friction between the Spring Valley Water Company and San Francisco on the peninsula and the Contra Costa Water Company and the East Bay cities on the mainland, were the underlying reasons for the formation of the Bay Cities Water Company, on October 21st, 1902. The Company acquired rights and large land holdings and outlined a project consisting of two parts—the Mt. Hamilton Project and the Coyote Project. The former is said to be capable of being developed to supply 22 000 000 gal. per day and the latter 40 000 000 gal. per day, or, combined, 62 000 000 gal. per day, approximately the quantity Mr. Grunsky planned to bring in by the initial Tuolumne, better known as the Hetch Hetchy, supply.

The Bay Cities Water Company made offers to both San Francisco and Oakland, but both were declined. Suits were instituted by the Spring Valley Water Company attacking the right to divert water from the Mt. Hamilton Project which is higher up but on the same Alameda Creek drainage area as that Company's Calaveras Reservoir and Sunol filter galleries, and by the land and riparian rights owners in the Santa Clara Valley, on the Coyote Project.

The Coyote Project, as proposed, consisted in collecting and storing surface waters in reservoirs to be constructed, one on Coyote Creek, another on Uvas Creek, and a third on Llagas Creek, all draining into the Santa Clara Valley. The decision of the Court in these suits will doubtless make it impossible to use this water in Alameda County.

The proposed Mt. Hamilton development would supply only 22 000 000 gal. per day, and therefore, even though the conflict with the interests of the Spring Valley Water Company did not exist, it would not be attractive, even for the East Bay communities alone. As a matter of fact, the water in question can be conserved more cheaply and delivered to any part of Greater San Francisco by the Calaveras Reservoir of the Spring Valley Company, because the latter is much nearer the mouth of Alameda Creek and the Bay cities.

In the course of these activities, the possibilities of the local underground waters were critically examined. H. L. Haehl, Assoc. M. Am. Soc. C. E., working in conjunction with C. E. Gilman, Assoc. M. Am. Soc. C. E., Manager, Edwin Duryea, Jr., M. Am. Soc. C. E., Chief Engineer of the Bay Cities and the Union Water Companies, and John W. Alvord, M. Am. Soc. C. E., Consulting Engineer, made exhaustive geological surveys, and reached practically the same conclusions, namely:

(1) That there are two distinct and disconnected bodies of underground water within the San Francisco Bay region, one reached by shallow wells less than 200 ft. deep, chiefly supplied by waters absorbed from stream overflow and the rainfall on the local alluvial

Mr. Robson.

fans, and to a much less, though considerable, extent by percolations through the joints and fissures of the rock rim and basin of the valley; and the other, locally known as the "Artesian" water, lying much deeper and in large measure supplied by the uptilted gravels of the Pliocene age, exposed at high elevations in the hills on the western side of the valley, where the rainfall is a maximum.

(2) That at the southern end the deep waters are truly Artesian, but the strength of the flow gradually diminishes toward the north, until in the region immediately south of Oakland the deep-seated strata no longer force their waters to the surface.

(3) That analyses of the waters of the two types taken from adjoining wells in general show no similarity, and the seasonal fluctuation of the respective water-tables are essentially different in time.*

(4) That local well-borers call these two underground water bodies "surface" waters and "Artesian" waters, respectively, and cast off the former in the region between San José and the southern extremity of the Bay, because they must be pumped.

(5) That the water supplied by percolations through the fault zones, joints, and fissures, in the distorted sedimentations of the rock rim and basin of the valley, although not the most important, is a considerable and material source of supply, and cannot be neglected in any proper consideration of the sub-surface water supply.

(6) That draft on the deep-seated "Artesian" waters west of the Alameda or Niles and San Lorenzo fans or "cones", is less than on the "surface" water, and that the former are not dependent for their supply on the surface flow of Alameda and San Lorenzo Creeks.

The Union Water Company, formed on December 21st, 1910, has put down a great many wells, scattered over the East Bay region from Richmond to Newark, and constructed several small distributing systems in various parts of the region. The Bay Cities Water Company is yet inoperative, and doubtless will never do any business in Greater San Francisco.

Essential Engineering Features.—The collection works of the Company, shown on Fig. 26, consist of 13 small pumping plants, of which 12 are now in use. In general, each well is an individual pumping plant with a gasoline engine or electrically-driven pump. The Company states that it has a total of 122 wells, in 14 groups, with a 24-hour test capacity of 26 000 000 gal. per day, and a safe daily draft of 19 000 000 gal. Of these wells, 12 are on the San Pablo cone, 65 on

* An interesting account of the geology and geological history of the region may be found in the Report of the Committee on the Geology of the Earthquake, in the Report on the Effects of the San Francisco Earthquake, *Transactions*, Am. Soc. C. E., Vol. LIX, 1907, pp. 216 *et seq.*, and in the Santa Cruz Folio, Geological Atlas of the United States Geological Survey, Washington. Reference may also be made to the discussion on the paper "Rain and Run-off near San Francisco, California," by C. E. Grunsky, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXI, 1908, pp. 522 *et seq.*

Mr. Robson.

the San Leandro cone, 5 on the San Lorenzo cone, 14 on the Niles cone, and the remainder outside these cones. Owing to contracts for watering lands north of Newark, the output from Plants 11 to 14, inclusive (about 11 000 000 gal. per day), are practically not available for use elsewhere. Of the remaining 8 000 000 gal. per day (which it is said may be used in supplying present urban communities) 2 666 666 gal. per day come from 23 wells, Plant 5, and 3 333 333 gal. per day from 33 wells, Plant 6.

The distribution works consist of about 91.5 miles of pipe, forming six different systems, as follows:

Three small systems in Richmond with a total of 10.4 miles in connection with Plants 1, 2, and 3; 2.9 miles connected with Plant 4; 52.6 miles as a network connected with Plants 5, 6, 8, and 9; and 25.1 miles connected with Plant 10; the last two systems are tied together. Almost all the mileage is supplying the south end of Oakland and San Leandro. The pumps deliver directly into the mains the pressure being controlled by automatic electric devices.

Of the pipe 39% is 2-in. and less, 72% 4-in. and less, 95.6% 8 in. and less, and the remainder is 10 and 12-in. Cast-iron pipe, from 4 to 10-in., comprises 24%, and the remainder is converse lock-joint and steel. There are 3 100 taps, of which 92% are metered, and 850 000 gal. per day are being supplied at a base rate of 32 cents per 1 000 gal. In addition, some hydrants have been put in at an annual rental of $35 per annum.

Other Water Supply Systems.

Besides the two systems just described, there are six public utilities controlled by and reporting to the State Railroad Commission supplying potable water in the East Bay region of Greater San Francisco, and three municipally owned—by the Towns of Newark, Niles, and Pleasanton—or nine systems altogether. These secure ground-water from wells, except Newark and Niles, which buy water at wholesale from the Spring Valley Water Company.

TABLE 5.

Company.	Place.	Assets, latest balance sheet.	Base rate per 1 000 gal.
Bay Point Light and Water Company	Bay Point	$25 000	0.30
Black Diamond Water Company	Pittsburg	67 931	0.20
Citizens Water Company	Niles	5 000	Flat rate.
Hercules Water Company	Hercules and Pinole	177 457	0.50
Port Costa Water Company	Port Costa, Concord, Martinez	756 971	0.30
San Lorenzo Water Company	Haywards	52 200	0.40

Mr. Robson.

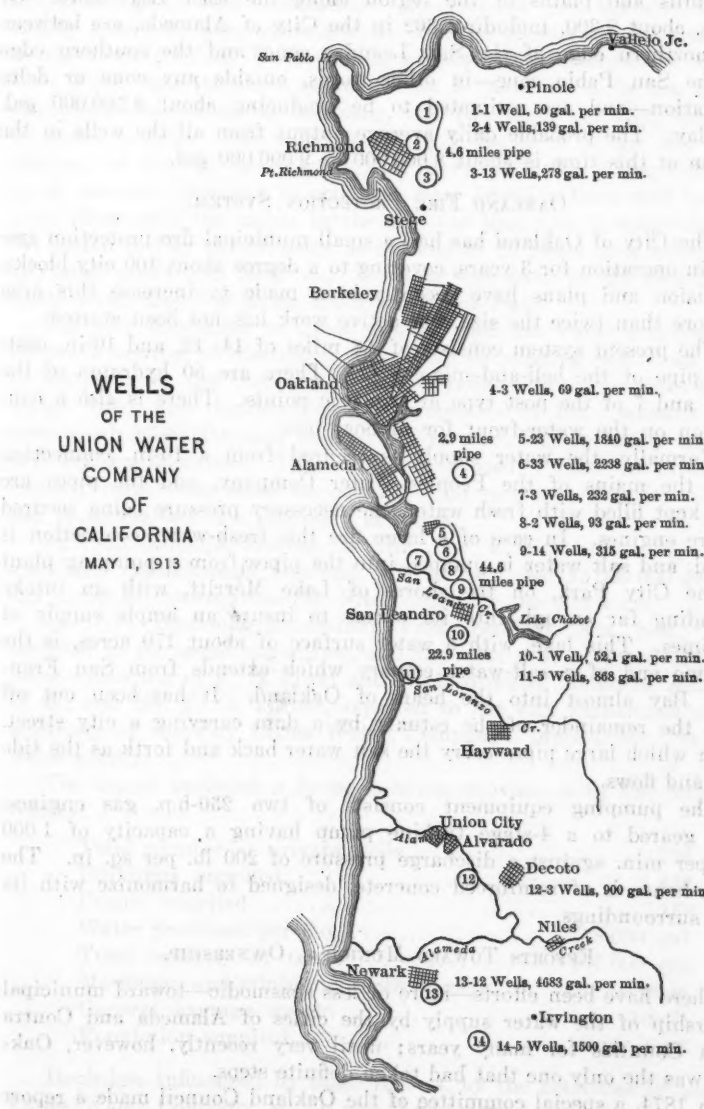

FIG. 26

Mr. Robson.

In addition, there are about 5 000 private wells in the western foot-hills and plains of the region along the East Bay shore. Of these, about 2 300, including 362 in the City of Alameda, are between the northern edge of the San Leandro cone, and the southern edge of the San Pablo cone—in other words, outside any cone or delta formation—and are estimated to be producing about 4 500 000 gal. per day. The probable daily average output from all the wells in the region at this time is about 8 000 000 or 9 000 000 gal.

Oakland Fire Protection System.

The City of Oakland has had a small municipal fire protection system in operation for 3 years, covering to a degree about 100 city blocks. Provision and plans have recently been made to increase this area to more than twice the size, but active work has not been started.

The present system consists of 3.8 miles of 14, 12, and 10-in. cast-iron pipe of the bell-and-spigot type. There are 50 hydrants of the flush and 7 of the post type at strategic points. There is also a connection on the water-front for fireboat use.

Normally, the water supply is secured from a 16-in. connection with the mains of the Peoples Water Company, and the pipes are thus kept filled with fresh water, the necessary pressure being secured by fire engines. In case of a large fire this fresh-water connection is closed, and salt water is pumped into the pipes from a pumping plant in the City Park, on the shores of Lake Merritt, with an intake extending far enough into its waters to insure an ample supply at all times. This lake, with a water surface of about 170 acres, is the extreme end of a salt-water estuary which extends from San Francisco Bay almost into the heart of Oakland. It has been cut off from the remainder of the estuary by a dam carrying a city street, under which large pipes carry the salt water back and forth as the tide ebbs and flows.

The pumping equipment consists of two 250-h.p. gas engines, each geared to a 4-stage turbine pump having a capacity of 1 000 gal. per min. against a discharge pressure of 200 lb. per sq. in. The pump-house is of reinforced concrete, designed to harmonize with its park surroundings.

Efforts Toward Municipal Ownership.

There have been efforts—more or less spasmodic—toward municipal ownership of the water supply by the cities of Alameda and Contra Costa Counties for many years; until very recently, however, Oakland was the only one that had taken definite steps.

In 1874, a special committee of the Oakland Council made a report on the local sources of water supply. It is interesting to note that, even as early as this, the merit of the Calaveras Creek dam site and

Mr. Robson.

water-shed was recognized clearly. The properties of the Contra Costa Water-Works were also investigated and found to promise an adequate supply. The committee recommended that the city immediately secure its own water system. Shortly thereafter, the president of the Contra Costa Water-Works proposed two alternatives to the city: First, that its plant be bought on a valuation to be set by five appraisers—two from the company, and two from the city, the four to choose a fifth. The value found by a majority of the five to be binding; or, second, that the city lend its credit to the Water Company to an amount sufficient to complete San Leandro Dam and connect it by pipes with the mains in the city—at that time 8 miles distant. An option to buy the property at the end of 10 years at a value fixed as stated would also be given. Nothing was done by the city in the matter, and thus Oakland's opportunity was lost.

The city continued to grow rapidly, and the water problem was always a source of discussion, but little or nothing was done until in March, 1900, the Company began its famous suit over rates before Judge Hart who decided that the properties of the Company were then worth $7 000 000 and allowed 7% interest, 2% operating expense, and 1% maintenance. This allowance caused a raise in rates, and many private wells were the result. The suit cost the city $32 000 and doubtless cost the Company as much.

In 1902, Rudolph Hering, M. Am. Soc. C. E., made a report for a citizens' committee of Oakland. He advised that 15 000 000 gal. per day could be drawn from the Niles cones for the city's use.

In 1903, Desmond FitzGerald, Past-President, Am. Soc. C. E., reported to the same committee, and the next year a Board of Engineers consisting of A. M. Hunt and J. M. Howells, Members, Am. Soc. C. E., and Mr. F. C. Turner, reported to the city authorities on the adequacy of the Bay Cities Water Company's project for Oakland's water supply.

The report included a house-to-house canvass, with the following results:

Total number of private wells	718
Buildings supplied	1 436
People supplied	7 180
Water produced per day	718 000 gal.
Total capacity of tanks	3 467 000 gal.
Maximum and minimum depth of wells	681 to 18 ft.
General average depth	100 ft.
Population supplied	10 per cent.

Doubtless influenced by these reports, by the activities of the Bay Cities Water Company, which was threatening to invade its territory, and by the controversy with the city over rates, the Contra Costa

Mr. Robson.

Water Company offered either to sell or lease to the city, at a value determined by two men who should select a third if necessary. The city took no steps, and the offer was finally withdrawn when rates were fixed on a valuation of $4 700 000, the city ignoring the decision of Judge Hart giving a value of $7 000 000. This case was then on appeal to the Supreme Court.

In June, 1904, Judge Gilbert granted an injunction against the rates fixed by the city, but required the Company to file a bond for $130 000.

In October, 1904, five water supply propositions were submitted to the city, chiefly by the Bay Cities Water Company which was making every endeavor to break into the territory; and in March, 1905, an election was held on an offer submitted by the Bay Cities Company. The campaign will long be remembered as the hottest and most spectacular known in Oakland. A large sum of money is said to have been spent by the opposing water companies. The vote resulted in 4 369 for and 5 207 against the proposition.

Since that time, the water problem has been before the people continuously. The suit started in 1904 has not yet been decided. The Contra Costa Water Company has merged with other companies, until now the corporation is known as the "Peoples Water Company". The Bay Cities Water Company has surrendered its activities to the Union Water Company.

The population has grown steadily, and the several communities on the East Shore now have the same water problem confronting them that Oakland left unsolved in 1874.

Financial and physical conditions make it almost impossible for one community to secure an adequate water supply without joining with others. This has been long realized, but the laws of California made no adequate provision for help. In 1909, a law following more or less closely the one under which the Metropolitan Water and Sewerage Districts of Boston and New York are operating, was passed by the State Legislature, but nothing has been done to organize a district because of alleged defects. At the request of the smaller communities, therefore, it was modified in 1911 to give them more representation. The present law permits any number of municipalities within the same county, as well as unincorporated territory, to unite and form a Municipal Water District.

In 1912, petitions were prepared and circulated to form a district, under the law of 1911, consisting of the municipalities of San Leandro, Alameda, Oakland, Emeryville, Piedmont, Albany, and some unincorporated territory, all in Alameda County. Sufficient signatures were finally secured, and it was thought a district would be formed. However, the Supervisors of Alameda County, who had the power to call the election, kept postponing the matter for one reason and another,

Mr. Robson.

until the present year, when an election was called for June. The Peoples Water Company put the stock control of the company, together with an option to sell its entire properties, the price to be fixed by the State Railroad Commission, in the hands of an Oakland bank.

Strong opposition to forming the district immediately appeared, a campaign of vituperation by the opponents followed, and attacks were made on the law, the water company, and the supporters of the measure. It seemed impossible to convince the electorate of the gravity of the situation, and even the majority of the newspapers were only lukewarm or actively opposed.

Due to the strenuous efforts of Mayor Heywood, of Berkeley, a majority of some 300 or 400 was given in favor of the district there, but this only nullified the adverse vote in the smaller communities, as Oakland returned a majority against the district of about 2 500. Less than 50% of the registered vote was cast. This defeat was a body blow to those who knew the conditions. Nothing has been done since, and it is not known what steps can or will be taken. A new law has been prepared, but should it be passed there will doubtless be as much opposition as before.

In the meantime, the Peoples Water Company was becoming more involved, financially, and in July, 1914, interest on its bonded indebtedness was defaulted. The affairs of the Company have been put in the hands of a committee of bankers, and protective committees of bondholders have been formed. No satisfactory reorganization plans have been given out, and the general financial conditions resulting from the war in Europe leave little of an encouraging nature apparent in the immediate future.

Conclusion.

No satisfactory solution of the water supply problem for the East Shore cities can be reached until these can be joined in one district or organization for that purpose. When this has been accomplished, such properties of the Peoples Water Company as are necessary must be purchased and the development of local sources completed. The district would then be in a position to purchase and distribute water from any source available.

Half of the total present and proposed supply of the Spring Valley Water Company comes from Alameda County sources. Under existing laws, if San Francisco purchases the Spring Valley Company, the taxes now levied by Alameda County on this property would not have to be paid by San Francisco. This would mean a large decrease in revenue for general county purposes.

After forming a district and purchasing the properties of the Peoples Water Company, the East Shore cities should buy the Ala-

Mr. Robson.

meda County system of the Spring Valley Company, thus relieving San Francisco of this portion of the purchase cost and making available a larger sum for acquiring distant mountain supplies.

It is a striking commentary on the foresight of the Spring Valley Company, when it is known that for years it has had a deeded right of way from its Calaveras Dam to the City of Oakland.

Mr. Le Conte.

L. J. LE CONTE,* M. AM. SOC. C. E. (by letter).—The writer is greatly interested in this timely paper. The author has certainly taken a very wide grasp of the whole complex situation, and in arriving at his conclusions has given due weight to all the important factors which influence a wise decision.

In comparing several schemes in which the construction cost is nearly the same, all the minor items—cost of operation, maintenance, depreciation, renewals, and incidental incomes—of course, are factors; but, when the first cost of construction is vastly greater in one case than in another, consideration of these smaller items can be omitted as they have no bearing whatever on the conclusion drawn.

Undoubtedly, the wisest policy for San Francisco is to develop, to the fullest extent possible, local supplies which will probably amount to 200 000 000 gal. per day, and be sufficient for 80 years to come. The city should then develop the pumping works at Moore's Landing on Old River, San Joaquin, and force the water up to Altamont Reservoir —capacity 1 000 000 000 gal. Thence supply mains should lead to the extensive natural gravel filter beds in Livermore Valley, and thence to the several large storage reservoirs in the Alameda Creek water-shed.

The first development will be for 50 000 000 gal. per day, which will be sufficient for 25 years more, or, say, until 2000 A. D. The cost of these new developments up to this time will be:

Peninsula	$40 000 000
Pumping works	10 000 000
Total	$50 000 000

thus making a unit cost for development of $200 000 per million gallons per day. Moreover, distant future expansions of the supply can be readily made at the same unit cost for development.

The East Bay region, by full development of all local sources, can obtain from 30 000 000 to 40 000 000 gal. per day, which will be sufficient for from 10 to 15 years to come. At the close of this period—1930—the best available outside source will be, likewise, at Old River, just above the junction of Indian Slough, some 12 miles above Marsh's Landing, which will be the site of the pumping works.

Thence, two supply mains will lead along the straits and bay shore to Berkeley, Oakland, and Alameda. The first development should

* Berkeley, Cal.

Mr. LeConte.

be for 100 000 000 gal. per day, which would call for the expenditure of $20 000 000. This additional supply would be sufficient for 60 years to come, or until 1975, and would show a unit cost of development of $225 800 per million gallons per day, delivered; and, moreover, the expansion of the supply, in the more distant future, can be readily made at the unit cost of $200 000 per million gallons per day.

These figures show conclusively that the distant Sierra supplies are undesirable, from every point of view, as will now be demonstrated.

In 1901, Mr. Grunsky reported that the Hetch Hetchy scheme, developed to 60 000 000 gal. per day, would cost $32 000 000, or $533 000 per million gallons per day, or nearly three times the cost of development of the local supplies near San Francisco. Likewise, in 1912, Mr. Freeman reported, with reference to the Hetch Hetchy scheme, that the first development for 160 000 000 gal. per day would cost (revised estimate) $64 000 000, showing a unit cost of development of fully $400 000 per million gallons per day. It would finally appear that this distant source of supply is vastly more expensive and is, therefore, undesirable.

Delta Sources.—The combined low-water flow of all the rivers naturally emptying into Carquinez Straits is now approximately 7 200 cu. ft. per sec., during the dryest seasons on record. This is simply the surface or visible flow, and does not include the underground supply which would probably increase it materially, if it were known; but, even the minimum (taken at 7 200), will give a reliable supply of 4 615 000 000 gal. per day. Now, it is a well-established fact that the large future hydraulic developments in the great Central Valley of California—in the way of irrigation, power, flood control, and extensive reclamation and irrigation works at and near Tulare Lake—will collectively tend to increase materially the low-water flow of all the rivers in the delta region.

The great works at Tulare Lake and vicinity will certainly add practically 10 000 sq. miles to the direct water-shed of the San Joaquin proper, and will certainly add 2 000 cu. ft. per sec. to the low-water flow of the river at a point just above Firebaughs. This result, combined with the underground return flow from the great irrigation fields on both sides of the river, will ultimately swell the low-water flow of the San Joaquin River to fully 6 000 cu. ft. per sec., thus greatly improving the low-water steamboat navigation on the entire river, to the everlasting benefit of the public in general.

The same beneficent results will also take place on the Sacramento River, and the writer is of the opinion, therefore, that fully 10 000 000 000 gal. per day can be considered as the reliable delta supply in the distant future.

Of course, subsidence and filtration, sooner or later, are to be expected for all supplies taken from the delta; but, naturally, this

Mr. Le Conte.

work is reduced to a minimum by placing the intakes on the south or Old River side, where long experience shows turbidity to be a minimum.

The quantity proposed to be taken from the delta supply, in the near future, is only 150 000 000 gal. per day, or 3% of the total, hence it can safely be said that there will be no trouble whatever from salt water.

In conclusion, it would appear that San Francisco and the East Bay region can both safely lay aside the idea of calling on the distant Sierra supplies for the next 100 years; and they will certainly be far better off financially by doing so.

EXTERNAL CORROSION OF CAST-IRON PIPE.

Discussion.*

BY MESSRS. KENNETH ALLEN, WILLIAM W. BRUSH, SAMUEL TOBIAS WAGNER, R. C. KELLOGG, A. D. FLINN, WILLIAM J. BOUCHER, AND GEORGE M. PURVER.

Mr. Allen.

KENNETH ALLEN,† M. AM. SOC. C. E.—With respect to the Atlantic City pipe, there are two old cast-iron mains, one 6-in., laid in 1881, and one 20-in. laid about 6 years later. Between 1902 and 1905, when the speaker was there, these pipes had deteriorated greatly, as described by Mr. Pugh. Soft spots in the metal were frequent, and although the pipes were in service and held the pressure, it was felt that it was not good policy to depend on them. In places the metal could be whittled like chalk, and yet no failure occurred in the 6-in. pipe when it was tested with a pressure of 75 lb. per sq. in.

With regard to the 40-in. steel main, which was laid in 1901 beside the cast-iron mains: that pipe, which was constructed of ¼-in. open-hearth plates, corroded much more rapidly. Two small perforations were discovered on February 2d, 1905; fourteen by September 1st, and twenty-two by January 1st, 1906. On September 1st, 1905, the speaker estimated that it would cost $345 340 to duplicate the three mains, and that their actual value then was $187 100, showing a deterioration of 46 per cent.

An inspector with a kit of tools walked the length of the mains from the pumping station and back—about 12 miles—every day; and when he found a hole in the steel main, he would whittle a small stick and plug it up—a very simple and effective expedient.

It seemed to the speaker at the time that, in view of the cost of the pipe—about $200 000—it would be desirable to preserve it, if possible,

* Continued from October, 1914, *Proceedings*.

† New York City.

Mr. Allen.

by a casing of 3½-in. reinforced concrete. This, it was estimated, would cost about $58 000, or $11 500 per mile, where exposed to the meadow conditions. Before deciding on this, however, it was concluded to make a test by covering in this way several short sections containing leaks, a contract for which was let before the speaker left. Later, however, it was decided to abandon this main altogether, and to put in a 42-in. wood-stave pipe. Still more recently, the 48-in. cast-iron pipe, which Mr. Pugh has referred to, has been constructed. Cast-iron has always been very difficult to handle on the meadows and, on account of vibrations from railway trains near-by, difficult to maintain in a tight condition; but it was believed that it would be much more durable than steel and, if raised above the surface of the meadows on cradles, would be more satisfactory on the whole than wood-stave pipe.

The author states that the "soil was free from organic acids". It is understood that analyses made by W. P. Mason, M. Am. Soc. C. E., some years ago, indicated the presence of vegetable acids which, of course, would promote corrosion of the iron. This action may have been increased at certain points by electrolysis, as tests, made in July, 1905, indicated a fairly constant flow of 30 amperes through the two cast-iron and the 30-in. steel mains toward the mainland where the current passed off to street railway tracks and a local water main. Whether the alteration in the metal referred to by the author may have been due partly to this cause is not known, but is suggested as possible.

The winter of 1904-05 was one of great severity, and the 12-in. main froze for the first time, breaking twenty-two lengths of pipe. It seems to the speaker quite probable that the loss would have been less if the pipe had been new and sound.

In the Annual Report of the Water Department dated August 1st, 1901, W. C. Hawley, M. Am. Soc. C. E., then Engineer and Superintendent, stated that:

"The cast-iron of the pipe has been changed in many places to a condition such that it can be cut by a knife, like chalk or graphite, and its specific gravity is only about 2.3. Some cases have been found where this condition extends entirely through the shell of the pipe; in others it extends from one-eighth to three-eighths of an inch in depth. This deterioration is not uniform in the same pipe; some of the pipes, in which the metal has in places changed through the entire thickness, having other places where no perceptible change has taken place. In some spots the tar coating is still to be found, but for much of the outer surface of the pipe, it has entirely disappeared."

Later, when the speaker succeeded Mr. Hawley in office, he found the conditions much the same, although no point was observed where this alteration extended through the entire thickness of the pipe. From a general consideration of these facts, the speaker would estimate 25

years as the extreme limit of the time during which dependence could be placed on cast-iron pipe under similar conditions, and is of the opinion that steel pipe coated as this was, with two layers of burlap and mineral rubber, is not suitable for use. Mr. Allen.

It may be of interest to add that while a sewer trench was being excavated along the water-front in Baltimore, several cannon balls varying from 4 to 6 in. in diameter were found several feet below tide-level, and, as there had formerly been a landing at this point, which subsequently was filled in, it seemed probable that these had been dropped from some vessel during the War of 1812. In spite of having remained in this position so many years, they were practically free from rust.

WILLIAM W. BRUSH,* M. AM. SOC. C. E.—New York City has more than 2 500 miles of pipe in its distribution system, and has had practically no difficulty from external corrosion. An examination, made about a year ago, of a length of 48-in. pipe which was laid in 1867 in Central Park, near the large reservoir, in ground that was low-lying and wet a good part of the year, showed the outside coating to be practically perfect. The general condition of the entire pipe system of New York City is such that the outside of the pipe generally shows no corrosion that would affect its life. Mr. Brush.

The interior of the pipe shows very materially the difference in effect of waters supplied to the different boroughs of New York City. Croton water has such slight corrosive effect on cast-iron pipe that sections of mains laid shortly after this water supply was introduced, in the early Forties, or in use some 60 years, show practically no corrosion. Therefore, there has been no necessity for cleaning these mains; whereas in Brooklyn, where the water has a comparatively high chlorine content, varying during the past 50 years from a maximum of about 25 parts per million to a minimum of about 8 parts, with an average for the past 20 years of possibly 15 parts per million, there is a corrosive or tuberculating effect, especially on pipe laid uncoated. The pipe laid in 1858 was mainly Scotch pipe, in 9-ft. lengths, and was uncoated. There was also some pipe cast in the United States at about that time and laid uncoated. Such pipe required cleaning, as the tubercles in a 6-in. pipe were of such size that a 2-in. rod could not be passed through the pipe without breaking off some of them. That pipe, when cleaned, was good, apparently, for another 50 years, as far as the strength of the wall limited the life. The rusting probably advances rapidly on the cleaned pipe. Thus, at Far Rockaway, pipe which had been laid from 20 to 30 years ago, and was cleaned about 10 years ago, now shows tubercles of a depth and volume equal to those found in pipe laid some 20 or 30 years

* New York City.

Mr. Brush. ago, which has not been cleaned. Apparently, with that particular water, tubercles developed in 10 years after cleaning, which would have taken 20 or 30 years to develop in the pipe as originally laid.

It is very important, however, to determine under what conditions rapid corrosion of the iron will take place on the exterior of the pipe. In many cases, even where protection would cost large sums, the cost of external protective measures for pipe lines would pay. On the other hand, there are cases where such protection would not pay.

Experience in New York City, where the pipes are frequently laid in ground-waters, especially along the water-front, indicates that there is no condition that would warrant any special method of protection.

Mr. Wagner. SAMUEL TOBIAS WAGNER,* M. AM. SOC. C. E.—The author has referred to pipe laid in Philadelphia in 1817. In 1897, about 1 000 ft. of this pipe, 22 in. in diameter, was removed from the bed of Pennsylvania Avenue on account of street changes. After 80 years of service, its external condition was almost perfect. It had been laid in a sandy and fine gravelly soil, on ground well above tide-water. The full section of the metal in the pipe was there, and although tubercles were rather freely distributed on the inside, the loss of waterway section was only about 4.2 per cent. The metal inside was generally in excellent condition.

Reference has been made to the effect of chlorine in the water on the internal condition of a cast-iron pipe. This is a new thought to the speaker, and for information, it might be interesting to add that the water in the Schuylkill River, which passed through this pipe line, has a chlorine content of about 5 to 6 parts per million.

The data presented by the author are of great interest, and serve to accentuate the necessity of studying local conditions before using any metal when corrosion is to be feared. There are many places where cast iron is the very best material that can be used to resist corrosion, and it would appear that the author believes that water pipe, when not exposed to the action of salt water, is one of them. Some cases of the resistance of this metal to ordinary atmospheric conditions are remarkable. In some of these, cast iron is still perfect where wrought iron and steel, similarly exposed, have rusted away. There can be no doubt that the resistance of the skin coat of silicious material is one of the chief reasons for its durability.

Mr. Kellogg. R. C. KELLOGG,† JUN. AM. SOC. C. E.—There has been so much advertisement and so much written in regard to the everlasting life of cast-iron pipe that information such as contained in this paper is of value, in order that the exceptions to the general rule as to the longevity of such pipe can be taken into consideration when using it.

* Philadelphia, Pa.
† Brooklyn, N. Y.

Mr. Kellogg.

Some years ago the speaker was familiar with conditions of quite severe pitting on a 60-in. riveted, steel main laid from Astoria to Ravenswood, Queens County, New York, to convey gas from the new Astoria Works to the Ravenswood plant. At the time, these pittings were attributed to electrolytic disturbances, but, in view of the information presented in this paper, it is only fair to assume that this was an error, and that the major causes were tidal action and the soil in which the main was laid, which was originally part of a salt marsh. This idea is somewhat strengthened when the speaker recalls the fact that an electrolysis survey did not seem to develop sufficient evidence that electrolysis was the sole cause of the trouble. He is familiar with several cases in Brooklyn where cast-iron gas mains have been taken up after having been in the ground from 50 to 60 years, such mains showing no signs of exterior corrosive injury. There are also several cast-iron gas mains crossing the Harlem River, at various points, all of which are covered by salt water and mud. Parts of these mains have been taken up, on account of accidental breakage, and show absolutely no effect of corrosive action.

From this it would appear that corrosion is caused, not only by soil of a certain character, and tide-water, but also that the air has an appreciable effect. The speaker is not familiar with any cases of internal corrosion, because his experience has been entirely with gas pipes, in which the interior surfaces are preserved by the deposition of liquid hydro-carbon compounds condensed out of the gas, due to friction and changes in temperature.

Mr. Flinn.

A. D. Flinn,* M. Am. Soc. C. E.—Some years ago, while visiting one of the yards of the Spring Valley Water Company, in San Francisco, the speaker was shown several lengths of wrought-iron pipe which had been taken from the ground after 20 years' service and was in perfect condition, both inside and outside. The pipe had been made in accordance with specifications by the Chief Engineer of the Company, and the asphalt coating had been made and applied also according to these specifications, the work being done with great care in all details. The speaker was informed by the engineer who accompanied him that pipe was frequently taken up, where changes in the system were necessary, and found to be in such excellent condition that, when necessary, it was re-used.

In connection with the Catskill Aqueduct, in laying pipe across The Narrows, from Brooklyn to Staten Island, a search was made for a coating that would be a little more durable than most of the known pipe coatings, and some inquiries gave hopeful accounts of one known in the trade as "bitumastic enamel". The pipe line, on

* New York City.

Mr. Flinn.

which this coating is being used, is now being laid, and the work will probably continue during the fall and next spring.

In respect to galvanizing as a means of protecting steel and iron, experience on the Catskill Aqueduct is encouraging. Steel-plate manhole covers, railings, and other objects which have been galvanized and exposed to the weather, have remained in good condition.

Mr. Boucher.

WILLIAM J. BOUCHER,* ASSOC. M. AM. SOC. C. E.—The use of cast-iron pipe is so general that the speaker believes that any data relating to the subject of corrosion will be of interest, perhaps, of value.

Until 1897 or thereabouts, Jersey City, N. J., was supplied with water from the Passaic River. The water was pumped from a station at Belleville, opposite North Newark, into and through a 36-in. cast-iron main laid alongside the Turnpike Road to a reservoir on Bergen Hill, Jersey City. This pipe was made by the Warren Foundry and Machine Company, and the letters, "W. F. & M. C., 1862", are still discernible to anyone with good eyesight. The pipe is supported, as described later, practically at the surface of the grass-and-weed-covered tidal salt marsh, which extends from the west side of Bergen Hill about 7 miles to the east bank of the Passaic River. It was laid during 1862 and 1863 and, with the exception of a few months in 1898, has conveyed water throughout its whole length since 1863. It shows no signs of pitting or disintegration, and is in practically a perfect state of preservation. With a pocket knife, the speaker removed a few patches of covering resembling asphalt. These patches covered only a minute fraction of the entire surface, and if the pipe was at one time entirely covered with a preservative, it has long since ceased to be of any value as the pipe, everywhere, is uncovered and the upper portion of its circumference plainly shows that it is used frequently as a foot-path.

The following description of the construction, etc., taken from the "Report of the Engineer of the Board of Water Commissioners, 1862-63," may be of interest:

> "Two rows of piles are driven, three feet apart, to a solid foundation, which is found at a depth varying from 12 to 20 feet below the meadow surface. The heads of the piles are then cut off 16 inches below the meadow and cross capped with 10 x 12-in. pine timber; upon this capping a brick pier 12 inches thick, 44 inches long, and 13 inches high, is laid up in hydraulic cement.
>
> "The pipe when placed upon this pier is securely held in its position by additional courses of brick work built up on its sides. The piling and capping are thus kept constantly immersed in water, rendering it perfectly secure from decay, and the joints of the pipe being just above the meadow surface enable them to be caulked without difficulty."

* New York City.

Mr. Boucher.

The pipes are 36 in. in diameter, $1\frac{1}{20}$ in. thick, and 12 ft. 5 in. long, averaging 4 800 lb. in weight. During 1862, 22 400 lin. ft. of completed main were laid, at a cost of:

Iron pipes at $37 per ton, delivered.....	$138 121.30
Contract for laying pipes, including piling, capping, brick foundations, and covering pipes with earth.	46 567.20

The object of the earth covering was to prevent the freezing of the water during the winter, but, according to the speaker's recollection, the pipe has had no earth covering for 20 years, and was conveying water when observed in October, 1914.

Mr. Purver.

GEORGE M. PURVER,* ASSOC. M. AM. SOC. C. E.—The speaker would like to ask Mr. Pugh, if he had any opportunity to observe the rate at which rusting of cast-iron pipe takes place. From the time a pipe begins to rust, does the rate of rusting remain uniform and vary directly with the time of exposure, or not; and would the author expect the same results under similar conditions?

The speaker believes that this paper should prove interesting and instructive to every member of the Profession, and it has suggested to him the idea that it would be desirable to urge the Society to appoint a "Special Committee on Deterioration of Structural Materials," such as stone, concrete, steel, cast iron, and wood.

Such a committee could gather all the data available on rusting of metals, rotting of wood, disintegration of stone and concrete, etc., and plot curves showing periods of time of their reliable service. It is possible that, with the assistance of coefficients established from observation of the conditions surrounding the material in use, one would be able to approximate the rate of deterioration.

The speaker does not recollect a single volume or pamphlet on this important subject that would comprise all the reliable data on the life of various structural materials, and yet in preparing an estimate or in evaluating an engineering enterprise, such data would furnish an important element.

---

THE CLARIFICATION OF SEWAGE BY FINE SCREENS.

Discussion.*

By Messrs. G. Bertram de B. Kershaw, W. L. Stevenson, George C. Whipple, C. A. Jennings, G. Franze and — Schaefer, George W. Fuller, J. X. Cohen, F. T. Robson, Alexander Potter, and Charles E. Gregory.

Mr. Kershaw.

G. Bertram de B. Kershaw,† M. Am. Soc. C. E. (by letter).—The first point noted, in reading Mr. Allen's valuable paper, is that it deals almost exclusively with large cities and their sewerage installations.

It is suggested in the paper that one of the conditions where fine-screening should generally be considered is "where the removal of all but the very fine solids will furnish a satisfactory effluent." It follows from this that the city contemplating fine-screening as a final process must have a suitable and sufficient body of diluting water available to carry out the purification process proper by oxidation, effected by abstraction of dissolved oxygen from the diluting body.

Conditions in England (where almost all the writer's first-hand experience has been obtained), are, as a general rule, unfavorable for the adoption of processes which throw the brunt of the purification on the body of water into which the sewage liquor is discharged.

English rivers, with very few exceptions, are small, in marked contrast to many of the rivers of the Continent; moreover, many of the smaller rivers receive sewage effluents at short intervals of distance throughout almost their entire courses, and are not in a condition to cope with any fresh burden of self-purification.

It is found to be the case, therefore, that screening is almost entirely confined to what may be termed "coarse" screening, that is, a screening

* This discussion (of the paper by Kenneth Allen, M. Am. Soc. C. E., published in August, 1914, *Proceedings*, and presented at the meeting of October 21st, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

† West Wickham, Kent, England.

Mr. Kershaw.

process only intended to remove the grosser solids, such as sticks, stones, coal, corks, potato peelings, and the like, which otherwise would be likely to lodge under sluice-valves and penstocks, and cause trouble; screens are also provided when the sewage is subsequently pumped, or, to protect the filter presses, where sludge pressing is carried out.

Such screens are generally of the bar type, cleaned by hand or automatic rakes, the openings between the bars being from about ½ in. to 1 in., and greater.

As giving a good idea of a very usual type of rough screen used at many sewage works in England, the following particulars regarding the Stratford-on-Avon sewage works (as being typical of a small English country town) may be of interest.

The screen at the pumping station is of ⅝-in. bars, spaced ⅝ in. apart, and it is inclined at an angle of about 20° with the perpendicular. Cleaning is effected by a system of traveling rakes attached to two endless chains, which elevate the screenings and tip them into a tumbril cart. It should be observed that the Stratford sewage is a strong one and contains a good deal of brewery waste.

Table 14 gives particulars relating to the screening operations.

TABLE 14.—ANNUAL QUANTITY OF SCREENINGS PRODUCED AT STRATFORD-ON-AVON SEWAGE WORKS.

Year.	Total yearly sewage flow, in millions of gallons.	Tons of screenings.	Tons, per million gallons.	Cost of Removing Screenings.		Rainfall for the year, in inches.
				Per million gallons.	Per ton.	
1908–09	126	100.5	0.70	1s. 3d.	1s. 7d.	21.06
1909–10	134	103.5	0.77	1s. 1d.	1s. 3¼d.	26.95
1910–11	136	99.0	0.73	5.9d.	8.1d.	25.17

Where special trade sewages have to be dealt with, such as those containing wastes from wool combing or the cotton industry, screening forms an important integral part of the sewage plant, but it should be observed that such screening is only to be regarded as ancillary or preliminary to the purification process proper, and it is intended merely to remove substances which might cause mechanical troubles at a later stage, reliance being placed on subsequent processes for real purification. It is, in fact, a process of abstraction rather than of purification, as generally understood.

The writer believes he is correct in saying that there are very few, if any, screening plants in England which are designed to effect other than a partial withdrawal of the larger suspended solids, such as are peculiarly likely to float and give an unpleasant appearance to the water into which they happen to be discharged. Certainly there are no

fine-screening plants capable of producing the results mentioned by Mr. Allen as being achieved in Germany by the best examples of fine screens. Mr. Kershaw

Fine-screening would appear to be peculiarly adapted to seaside resorts in England, where bathing is enjoyed.

The Royal Commission on Sewage Disposal,* for which the writer has been Engineer for some sixteen years, in dealing with standards, states as follows:

"But we think it of great importance, if only for the sake of the appearance of the river, that the grosser solids, such as undisintegrated fæces, paper, etc., should, as far as possible, be held back, and the provision of some effective form of screening apparatus should be insisted on wherever practicable."

There is no doubt that, when the treatment of sewage by dilution is better understood in England, fine-screening will become of considerable importance. Screening as a final process in certain cases is likely to be carried out when the Commission's reports have been digested by the English Local Government Board. At present, there is some uncertainty as to how "dilution" schemes would be received officially.

The following statement shows the degree of dilution and limiting figures for suspended solids in sewage liquors, laid down by the Commission for cases where disposal by dilution is to be countenanced.

Dilution.	Suspended solids, in parts per 100 000.
Exceeding 150 volumes and less than 300 volumes.....	6
Exceeding 300 volumes and less than 500 volumes.....	15
Exceeding 500 volumes.....	Crude sewage could be discharged subject to such conditions, as to the provision of screens or detritus tanks, as might appear necessary to the central authority.

It may be noted that the following figures show what would be considered good tank liquors in England, assuming a domestic sewage of average strength, containing some 35 parts of suspended solids per 100 000, to have been treated.

Treatment.	Parts per 100 000.
Septic tank treatment.....	10 to 15
Continuous flow settlement.....	10 to 15
Quiescent settlement	5 to 8
Continuous flow precipitation.....	3 to 6
Quiescent precipitation	1 to 4

* Eighth Report, Royal Commission on Sewage Disposal, p. 12, para. 42.

Mr. Kershaw.

It should be observed that, for the determination of the suspended solids, a Gooch crucible, packed with asbestos floss, is used.

An English domestic sewage of average strength contains about 35 parts of suspended matter per 100 000, but the quantity is variable. A large part of these solids is usually very finely divided. The actual fineness will depend to a great extent on the sewerage system, the distance the sewage has traveled, whether pumped (which often breaks up the solids and increases colloidal matter) or flowing by gravitation, nature of street surfaces, if the combined system of sewers is in use, temperature, and many other variable factors; but a large proportion of the finer suspended solids will almost invariably pass with ease through a mesh of $\frac{1}{50}$ in. or even less; and, with a septic sewage, such as sometimes results in hot weather when the sewage has traveled far, the finest screens will effect very little useful work.

In most sewages, trade wastes of various kinds form a feature, and the suspended solids in the sewage may then be very greatly increased, and vary from hour to hour. Again, a population served entirely by water-closets will, as a rule, contribute much more screenable matter than where the whole of the fæces and paper does not enter the sewers.

The writer has followed the Chicago sewerage problem for some time past, and the percentage of removal effected by Mr. Jennings' screen (63%) seems very high, notwithstanding the fineness of the mesh (40 per in.). Possibly it is accounted for by the nature of the sewage, which presumably contains suspended matter of a uniform nature and size, such as masticated hay, etc. If this is so, such screenings would be likely to resist decay, owing to the large quantity of cellulose matter they would contain.

The nature of the suspended solids in a sewage varies considerably. From 40 to 60% of the suspended matter in most English sewages consists of mineral or inorganic matter, practically innocuous by itself (excepting as regards the silting up of waterways), but it is found that these particles carry with them, as a kind of envelope, a considerable quantity of organic impurity in solution, and they exercise a de-oxygenating action on rivers and streams, albeit not such a sustained action as solids of organic origin.

When dilution is relied on to complete the purification of a settled or screened sewage liquor, the main essential is to keep the bulk of the suspended matter in suspension in the river water until it has become oxidized or nearly so.

The capacity of a clean river to endure pollution without visible signs of nuisance appears to be closely related, among other things, to its depth, velocity, power of transportation, temperature, and aquatic plant, fish, and insect life.

Mr. Kershaw.

If the mud near the borders of a river receiving a certain quantity of pollution be examined, it will generally be seen to consist of very fine particles of black mud, overlaid by a thin layer of brown (or nearly oxidized) mud on the surface, where it has been intimately in contact with the dissolved oxygen in the river water. How fine much of this mud is, may be judged by mixing some of it with tap water and straining the liquid through a handkerchief into a glass; much of the fine matter will be found to pass through the linen with the water.

It is mainly these very fine solids which cause de-oxygenation troubles in sluggish rivers or sluggish reaches of rivers, when they become deposited, and it is very difficult, with good tank treatment, to keep them back, unless precipitants are used.

In England, however, there are instances where, owing to favorable local conditions in a river—such as volume and velocity—such fine suspended matter might be discharged without any perceptible damage to the river, and in such cases fine-screening of the nature indicated by Mr. Allen would be of marked value.

The writer has seen examples where the removal of the tank effluent outfall from the bank of a river to a point some distance from the shore would have admitted of fine-screening in lieu of tank treatment. It is quite possible to foul a strip of river seriously by the discharge of tank liquor or sewage close to the shore, whereas the admixture of screened sewage with the whole volume of river water would suffice for purification purposes.

With small rivers in England, the writer has no doubt that less damage would result to the rivers by passing fresh sewage from a small community into them, after efficient screening, than, as is often done, by passing the sewage through a septic tank and thence to the river. Septic tank treatment almost invariably results in the production of sulphuretted hydrogen, which has the property of taking up dissolved oxygen from water very rapidly. An Imhoff tank would probably solve such problems, but screening would be cheaper.

As Mr. Allen carefully points out, screenings consist largely of organic matter, and considerable weight must be attached to the fact that, with suitable forms of screens, organic matter, such as fæces, etc., are removed at once from contact with the liquid portion of the sewage, whereas, with tank treatment, much of this organic matter is left in contact with the liquid in the tank for some considerable time, more and more of it going into solution as fermentation proceeds.

On the other hand, screenings are more likely to attract dipterous insects for ovipositing than sludge; still, they might be deterred by the use of bleaching powder or some similar chemical. Both screens

Mr. Kershaw.

and screenings should be roofed in wherever possible, for the above reason, quite apart from danger of nuisance from smell.

The results obtained by fine-screening in Germany, cited by Mr. Allen, appear to show an extraordinary efficiency, and it is difficult to imagine such a percentage as 90.

Experiments carried out at Leeds, England, with a fixed-mesh screen of 30 per in., inclined with the sewage flow, appeared to keep back a considerable proportion of the suspended matters in the sewage, but "although the accumulation seemed bulky, it was found on drying to represent less than 10% of the suspended matter in the sewage." (Leeds sewage contains about 60 parts of suspended matter per 100 000.) It may be noted that the clear liquid of a sample of average Leeds sewage which had been passed through filter paper still contained in solution about 50% of the original impurities, becoming dark-colored and putrefying.

There can be no question that screenings and sludge stand on an entirely different footing as regards manurial value and fat content. Screenings consist largely of nitrogenous matter, and usually contain little mineral matter; whereas, in sludge the solids are generally 50% inorganic, and it is worth just what can be obtained for it.

The fat content of the screenings at Hamburg is well brought out in Table 1, showing the composition of grit and screenings, the average being nearly 5 per cent. In Table 2 it would be interesting to know whether the nitrogen and phosphates are in as readily available form for plant life as in artificial manures. The manurial constituents of most sewage sludges appear to be in an inert and slowly-acting condition, and the writer has always considered that a great part of any of the value that sewage sludge may possess, is due to its physical and mechanical, rather than its manurial, action on soils.

Regarding the Carshalton screen, it should be observed that all these screens are used for either crude or grit-settled sewages. The writer does not know of any plants in which they are used for screening tank liquors. It may be noted that this screen is driven by a water-wheel actuated by the flow of sewage, and the speed at which the screen travels is automatically adjusted to the work required of it.

This is a matter of importance, because, if a screening apparatus reduces the velocity of the sewage flow beyond a certain point, settlement of suspended matter will take place up stream from the screen; it is of importance, therefore, for automatic screens to work at a rate which will allow the sewage flow to be maintained at a velocity sufficiently high to keep the solids in suspension. If, owing to too slow a motion of the screen, or temporary insufficient area of mesh openings (such as might result from paper flattening against the meshes), the decrease in velocity causes the sewage to head up, and, consequently,

adjacent storm overflows may be brought into operation, especially if the gradient of the main outfall sewer is a slack one. Mr. Kershaw.

It is a most complicated matter to arrive at the real efficiency of screens, and this is largely due to the difficulty of obtaining reliable average samples, and of procuring accurate analytical figures covering a long period of experimentation.

The accurate determination of suspended solids is a tedious process, and it might be possible to use a centrifuge in order to save time. If this was done, however, results obtained with a sewage containing suspended solids of a granular nature would scarcely be comparable with those obtained elsewhere with a sewage containing flocculent suspended solids, although they would be reliable for the one place if the suspended solids were constant in character.

The most important point appears to the writer to be, not how great a quantity of screenings is removed per million gallons of sewage, but how much suspended matter is left in the screened liquor. A screen may appear to remove a large quantity of matter from the sewage (as in the Leeds experiments), and yet, on carefully analyzing the screened liquor, the quantity of suspended solids is usually found to be high.

It is of vital importance, therefore—and it is noted that Mr. Allen lays stress on this point—that, in any screening experiments, the quantity of suspended solids, both in the raw sewage and in the screened liquor, should be most accurately determined, and for a considerable period, during both hot and cold weather. During cold weather one would expect more screenings to be removed than in hot weather, and, turning to the Dresden results, given in Table 10, if the weight of dry material in the screened liquid be subtracted from the weight of dry material, as in Table 15, it will be seen that the matters removed by screening reached a maximum in the coldest weather, and this is what one would have expected, because fermentation and its power of breaking down organic matter is then at a low ebb.

TABLE 15.

Period.	Weight of dry material in raw sewage, in grammes.		Weight of dry material in screened liquid, in grammes.	Weight of dry material removed by screens, in grammes.
March, April, May	50.96	less	41.40	= 9.56
June, July, August	61.42	"	50.78	= 10.64
September, October, November	81.71	"	59.13	= 22.58
December, January, February	99.41	"	51.33	= 48.08

It is essential, in any comparative trials of screens, that all samples should be average ones, that is, drawn every hour or oftener throughout

Mr. Kershaw.

the 24 hours, according to the rate of flow of the sewage, otherwise very misleading results may follow; further, the samples of raw sewage and of screened sewage should be strictly corresponding ones; these can be ensured as a rule by the use of a coloring dye, such as fluorescin (green) or eosin (red).

In connection with this last point, the figures of analysis given in Table 4 for chlorine, show that the samples were not corresponding ones, the figure for the raw sewage being 262.6, and that for the screened sewage, 279.4; these figures should have been practically identical. It is to be noticed that there is no material difference in the polluting property of the raw and screened sewages, judged by the figures for "oxygen consumed."

Regarding the results given in Table 4 with reference to the Geiger screen, it appears probable that the rolling action of the vanes, as the screenings pass to the axis, tends to comminute, or perhaps to send into solution, some organic matter, thereby increasing the strength of the screened sewage.

Some methods of cleaning screens leave much to be desired, from this point of view, and sewages are sometimes stronger as regards dissolved impurities after screening than before, from this cause. Good management must always be forthcoming, if the best results are to be obtained.

In order to gain a strictly scientific comparison between various screens, it would seem that the only way would be to test them all on the same sewage; even this procedure might not hold good, because a particular type of screen might be better adapted to some sewages than to others.

In any case, trials of screen efficiency carried out with one sewage would be costly, because they would need to be tried on a working scale to yield useful results.

A point needing special attention would be the moisture contained in the screenings, and it would seem advisable to devise a standard method of draining, whereby the screenings in each test would be drained for a given time on a specially formed drying area before being sampled for analysis; moreover, the sub-sampling and sampling of the screenings would require very great care.

The hourly sewage flow and the velocity through the screens would need to be carefully recorded in all trials, because solids are apt to be forced through even fine screens under conditions of heavy sewage flow.

Table 12, summarizing the data relating to the screens discussed by Mr. Allen, is valuable, and the cost of operation does not anywhere appear to be excessive; it is to be observed, however, that the whole question of efficiency depends on the sampling and analysis, and the accuracy with which these are done.

Mr. Kershaw.

Will Mr. Allen state whether the figures in Table 12 for cost of operation per million gallons include interest on capital outlay, or depreciation? The writer is of the opinion that they do not.

It would have been most interesting if the author could have given columns showing the volumes of water into which the screened liquors were discharged, and the visual effect produced on the water and banks. The writer is well aware, however, of the difficulties involved in obtaining reliable information on these points.

The writer is in general agreement with Mr. Allen's conclusion, although rather doubtful whether a 30% removal of total suspended solids from an average domestic sewage is not too sanguine an estimate to be uniformly attained.

Mr. Allen is to be congratulated on a most interesting and instructive paper. A vast amount of time and labor must have been expended in collecting and assorting the minute data it contains, and it would be well if more engineers in England would follow Mr. Allen's example and go and see for themselves anything new connected with sewage purification and disposal plants.

A feature of this paper is the excellence of the half-tones with which it is illustrated.

Mr. Stevenson.

W. L. STEVENSON,* Assoc. M. AM. SOC. C. E. (by letter).—During 1909-10, the Bureau of Surveys of Philadelphia operated a sewage testing station in connection with the investigations being carried on for the preparation of a comprehensive plan for the collection, treatment, and disposal of the sewage of that city.

Among the processes studied was fine-mesh screening. The observations throw light on the second and third functions of fine screens mentioned by Mr. Allen, and also on the character of the sludge produced in subsequent sedimentation, and the efficiency of fine-screening as a preparatory treatment for subsequent disinfection.

The sewage used in the testing station was collected by a separate system of sewers from a territory partly residential and partly devoted to the textile industry, and contained a considerable quantity of trade wastes.

The fine-mesh screen consisted of a cone covered with red metal cloth, 32 meshes per inch, and having clear openings ½ mm. square. Sewage which had been removed from the side at about mid-depth of the flow in the intercepting sewer was raised to the testing station by a plunger pump and applied to the screen through twenty-four ¼-in. nozzles. No attempt was made to design a screen for practical use, the screenings being washed away to a trough by the splashing of the jets; but screened sewage was obtained for subsequent study. On an average, the sewage applied to the screen contained 200 parts

* Philadelphia, Pa.

Mr. Evenson.

per million of suspended matter, as measured by the Gooch crucible; and the average effluent contained 133 parts per million. The functions of this screen on subsequent treatment of the effluent were as follows.

"2. The Removal of Solids That Otherwise Would Cause the Frequent Subsequent Clogging of Sprinkler Nozzles or Filters."—The screened sewage, after plain sedimentation in a horizontal tank, was applied to a percolating filter through two square spray Taylor nozzles. During 9½ months service, these nozzles were never clogged; whereas, the same crude sewage after similar sedimentation without fine-screening caused frequent nozzle-clogging from match sticks, wool fibers, etc. The interstices of the media in the filter to which the screened and settled sewage was applied, were invariably cleaner and freer from sludge than those in filters to which only settled crude sewage was applied.

"3. The Removal of Material Likely to Promote the Formation of Scum in Subsequent Tank Treatment."—Two horizontal-flow, sedimentation tanks, each provided with baffle- and scum-boards of identical construction and operated at the same rates, received as influents, respectively, crude sewage and the effluent of the fine screen. In the tank receiving crude sewage a scum always formed a few days after it was put in service, and before cleaning the tank it usually attained a thickness of more than 1 ft. It was composed of a leathery mat of wool fibers, hops, and other sewage matters which were light enough to float.

The surface of the tank receiving the screened sewage always remained clean and free from any floating matters. This had an effect on the quality of the effluent. Septic action developed much sooner in the tank receiving unscreened sewage, and the effluent was more deoxidized than that from the tank receiving screened sewage.

Naturally, the effluent of the tank receiving screened sewage was lower in suspended solids than the other, and its quality was also more uniform. Sudden increases in suspended solids in the crude sewage produced a synchronous increase in those in the effluent of the tank receiving crude sewage; but no change was noted in the effluent of the tank receiving screened sewage, as the screen relieved the tank from these peak loads of suspended matter.

The Effect of Fine Screening on Sludge Formed in Subsequent Tank Treatment.—On an average, 4.07 cu. yd. of sludge of 1.053 specific gravity and containing 86.1% of moisture, were deposited from each 1 000 000 gal. of crude sewage settled, and 4.65 cu. yd. of sludge of 1.036 specific gravity and containing 90% of moisture, were deposited from each 1 000 000 gal. of screened sewage settled. The lower specific gravity and higher water content of the sludge from the screened sewage was due to the fineness of the particles of which

Mr. Stevenson.

it was composed. Each cubic yard of the crude sewage sludge contained, on the average, about 990 lb. of dry residue and 790 lb. of the screened sewage sludge.

The effect of the fine screen, therefore, was to increase the volume of sludge by 14%, but to reduce the quantity of dry solids deposited by 20 per cent.

The screened sludge, however, dried more readily than the crude sludge, due to absence of wool fibers which prevented the formation of deep cracks in the latter. When removed from the drying beds, the quantity of screened sewage sludge was less than that of crude sewage sludge.

Efficiency of Fine Screening as a Preparatory Process to Disinfection.—Experiments were carried on to determine the quantity of calcium hypochlorite required to disinfect fine-screened sewage, settled crude sewage, and settled screened sewage. The results were divided into two groups: First, a quantity of disinfectant which should be added during an epidemic of intestinal disease to insure protection to communities below the point of discharge; and, second, a quantity which would destroy more than 95% of the *B. Coli* at a moderate cost. The results are given in Table 16,

TABLE 16.

Kind of sewage.	Available chlorine added, in parts per million.	Total Number of Bacteria per Cubic Centimeter, on Gelatine at 20° Cent., in 48 Hours.			*B. Coli* per Cubic Centimeter, as per Jackson's Presumptive Test.		
		Initial.	Final.	Percentage remaining.	Initial.	Final.	Percentage remaining.
Fine-screened sewage....	12.4	2 470 000	337	99.99	121 000	20	99.98
	6.0	2 060 000	181 000	91.21	149 000	7 470	95.42
Settled crude sewage....	11.9	2 450 000	350	99.99	143 000	10	99.99
	5.4	760 000	31 000	95.92	67 000	745	98.89
Settled screened sewage.	12.0	2 130 000	310	99.99	86 000	20	99.98
	4.3	660 000	22 500	96.59	317 000	1 350	99.57

and show that sedimentation of the sewage was more efficient as a preparatory process to disinfection than fine-screening; but that, in cases where the receiving body of water is capable of assimilating, without nuisance or detriment, the effluent of a fine-mesh screen containing particles not larger than 1 mm., it is practical to disinfect it. Experiments have been made to show that it is not practical to disinfect sewage containing particles larger than 1 mm.

Summary.—The results of the experiments made by the Bureau of Surveys show that the use of a screen of 32 meshes per inch prior to sedimentation produces an effluent which will not clog the nozzles

Mr. Stevenson.

or media of a percolative filter; prevents the formation of scum in subsequent tank treatment; causes a uniform quality of tank effluent, regardless of irregular quantities of suspended matter in the crude sewage; yields a sludge from subsequent sedimentation higher in moisture and of greater volume, but containing less dry solids, than from the sedimentation of crude sewage; and is a satisfactory preliminary treatment for subsequent disinfection.

These data are merely statements of facts. The application of fine-screening of sewage to any particular case is an engineering problem to be determined by the local needs and conditions.

The writer wishes to express his appreciation of the valuable data which Mr. Allen has furnished in this paper.

Mr. Whipple.

GEORGE C. WHIPPLE,* M. AM. SOC. C. E. (by letter).—This is an excellent paper on sewage screening, and should form the nucleus for some interesting discussions. With the author's main contention, that fine-screening is destined to play an important part in sewage treatment in America, the writer is in hearty sympathy. That was the conclusion which he reached a number of years ago after a trip to Europe which was referred to in a discussion presented to the Society in June, 1906.

In the prevention of the pollution of streams, lakes, and harbors it is necessary to have laws which govern the discharge of sewage and trade wastes into such bodies of water. These laws must not be discriminatory, but, in the interest of fairness, must be general in their application, and yet each city or town must be permitted to take charge of its local facilities for sewage discharge, using them to the limit, but with due regard to proper sanitation. Undoubtedly, there are local situations where the discharge of raw sewage into streams will do no harm, but it is difficult to frame and execute laws which will fairly separate the places where no sewage treatment is needed from those where treatment of some kind is necessary. From an administrative point of view, it may be better to make the law general that no raw sewage shall be discharged into our waterways, and leave the nature of the treatment in each case to some properly constituted authority. In doing this it will be necessary to give a broad meaning to the term "sewage treatment" and allow it to cover, not only the more elaborate processes of purification, but also the simpler methods of coarse screening.

Between raw sewage and that which has passed through coarse screens there is no material bacteriological difference, and we might almost say the same with reference to raw sewage and that which has passed through the fine screens described by the author. Yet the process of screening is so inexpensive, and it does so much to

* Cambridge, Mass.

Mr. Whipple.

avoid the obvious signs of pollution by the removal of the lighter and the grosser solids, that there are few cases where the process is not justified by its results. By giving this liberal interpretation to the expression "sewage treatment" it will be easier to obtain legislative action relating to the control of sewage discharge. The engineers who recently advised the International Joint Commission, in the matter of the control of sewage disposal for communities on the boundary waters between the United States and Canada, took this view when they formulated the following guiding principles. It will be seen that they were worded so as to include screening as a form of treatment. For this reason they may be appropriately inserted in this discussion.

"NEW YORK, *June 27, 1914.*

"To the INTERNATIONAL JOINT COMMISSION.

"GENTLEMEN: The following statements represent the essence of the opinions given by us before your honorable commission at the conference held in New York on May 26 and 27, 1914:

"1. Speaking generally, water supplies taken from streams and lakes which receive the drainage of agricultural and grazing lands, rural communities, and unsewered towns are unsafe for use without purification, but are safe for use if purified.

"2. Water supplies taken from streams and lakes into which the sewage of cities and towns is directly discharged are safe for use after purification, provided that the load upon the purifying mechanism is not too great and that a sufficient factor of safety is maintained, and, further, provided that the plant is properly operated.

"3. As, in general, the boundary waters in their natural state are relatively clear and contain but little organic matter, the best index of pollution now available for the purpose of ascertaining whether a water-purification plant is overloaded is the number of *B. coli* per 100 cubic centimeters of water expressed as an annual average and determined from a considerable number of confirmatory tests regularly made throughout the year.

"4. While present information does not permit a definite limit of safe loading of a water-purification plant to be established, it is our judgment that this limit is exceeded if the annual average number of *B. coli* in the water delivered to the plant is higher than about 500 per 100 cubic centimeters, or if in 0.1 cubic centimeter samples of the water *B. coli* is found 50 per cent. of the time. With such a limit the number of *B. coli* would be less than the figure given during a part of the year and would be exceeded during some periods.

"5. In waterways where some pollution is inevitable and where the ratio of the volume of water to the volume of sewage is so large that no local nuisance can result, it is our judgment that the method of sewage disposal by dilution represents a natural resource and that the utilization of this resource is justifiable for economic reasons, provided that an unreasonable burden or responsibility is not placed upon any water-purification plant and that no menace to the public health is occasioned thereby.

Mr. Whipple.

"6. While realizing that in certain cases the discharge of crude sewage into the boundary waters may be without danger, it is our judgment that effective sanitary administration requires the adoption of the general policy that no untreated sewage from cities or towns shall be discharged into the boundary waters.

"7. The nature of the sewage treatment required should vary according to the local conditions, each community being permitted to take advantage of its situation with respect to local conditions and its remoteness from other communities, with the intent that the cost of sewage treatment may be kept reasonably low.

"8. In general, the simplest allowable method of sewage treatment, such as would be suitable for small communities remote from other communities, should be the removal of the larger suspended solids by screening through a one-fourth inch mesh or by sedimentation.

"9. In general, no more elaborate method of sewage treatment should be required than the removal of the suspended solids by fine screening or by sedimentation, or both, followed by chemical disinfection or sterilization of the clarified sewage. Except in the case of some of the smaller streams on the boundary, it is our judgment that such oxidizing processes as intermittent sand filtration, and treatment by sprinkling filters, contact beds, and the like, are unnecessary, inasmuch as ample dilution in the lakes and large streams will provide sufficient oxygen for the ultimate destruction of the organic matter.

"10. Disinfection or sterilization of the sewage of a community should be required wherever there is danger of the boundary waters being so polluted that the load on any water-purification plant becomes greater than the limit above mentioned.

"11. It is our opinion that, in general, protection of public water supplies is more economically secured by water purification at the intake than by sewage purification at the sewer outlet, but that under some conditions both water purification and sewage treatment may be necessary.

"12. The bacteriological tests which have been made in large numbers under the direction of the International Joint Commission indicate that in most places the pollution of the boundary waters is such as to be a general menace to the public health should the water be used without purification as sources of public water supply or should they be used for drinking purposes by persons traveling in boats.

"13. It is our judgment that the drinking water used on vessels traversing boundary waters should not be taken indiscriminately from the waters traversed, unless subjected to adequate purification, but should be obtained preferably from safe sources of supply at the terminals.

"14. While recognizing that the direct discharge of fecal matter from boats into the boundary waters may often be without danger, yet in the interest of effective sanitary administration it is our judgment that the indiscriminate discharge of unsterilized fecal matter from vessels into the boundary waters should not be permitted.

"Yours, respectfully,

"GEORGE W. FULLER.
EARLE B. PHELPS.
GEORGE C. WHIPPLE.
W. S. LEA.
T. J. LAFRENIERE."

Mr. F. A. Dallyn, who was one of the six consulting engineers to advise the Commission, presented a minority report, in which he eliminated Paragraphs 5, 7, and 11, and made a few slight changes in some of the other paragraphs. Mr. Whipple.

Screens have also an important application in the treatment of trade wastes. In fact, they are already used to a considerable extent in factories which handle fibrous material in a wet way. In England the writer has seen screens of the drum type or the cylindrical type operated so effectively as to produce a saving of material equal in value to the cost of operating them.

The author has made allusion to the extensive development of the art of screening in Germany. This may be illustrated by the following statistics collected by Mr. Sylvester Schattschneider, of the Department of Sanitary Engineering, Harvard University, as a part of a study of the sanitary conditions of certain German rivers.

Tables 17 and 18 show the number of sewage disposal plants of various kinds above the intakes of the water-works named in Column 1. In general, these have been classified according to the final process used in the treatment. The simplest form of treatment is that mentioned in Column 2, namely, coarse screens. The efficiencies of the treatments increase in order from left to right, the best effluents being obtained by broad irrigation and intermittent sand filtration. The figures do not indicate the number of screens in use, but only the number of plants where screening is the final process.

The figures include only cities which are in Germany. Some of the more important catchment areas extend into neighboring countries, so that the total number of treatment works above a given intake may slightly exceed the figures given.

Germany has followed the general principle of some treatment for all sewage, and for each the simplest treatment that will suitably protect the waterways. It will be noticed, also, that Germany does not depend on sewage treatment to protect water supplies, but on water filtration and the use of ground-water. The writer believes that, for many sections of the United States where the waterways are large, this is the best general principle to follow. The treatment selected for any given case must be adequate for the most adverse conditions, and it should not be forgotten that in many sections of the United States the streams reach a minimum flow far below that of German rivers, and also that the summer temperatures of the water in the United States are in general higher than in Germany and England. The German rivers differ from those of England in having swifter currents. Consequently, a simpler form of sewage treatment is permissible.

During the summer of 1914, Mr. Theodore R. Kendall, a recent graduate of the School of Engineering of Harvard University, has

Mr. Whipple.

Mr. Whipple.

visited many of the sewage disposal plants of Europe, and the writer takes pleasure in presenting the following notes on visits which he made to places not mentioned by the author.

Eberswalde.—At Eberswalde two sets of screens precede the settling and biological treatment, the first set consists of round bars 2 cm. in diameter and with 3-cm. spacings. This arrests the coarser material and paper, and is cleaned by hand when necessary. Immediately beyond is a Reinsch-Wurl screen with 3-mm. openings. All screenings are elevated to the surface and discharged into metal cans holding about ⅓ cu. yd. each. The screenings sell for about 2.5 cents per can. There was no odor about this plant when the temperature was 35° cent. (95° Fahr.). Stadtbaurat Arndt mentioned that before screens were installed the sedimentation basins had to be cleaned every 3 weeks; now they can be used from 4 to 5 months. Population, 37 000.

Düsseldorf.—The sewage of Düsseldorf is approximately 1 cu. m. per sec., giving a velocity of 0.78 m. per sec. in the main outfall. The flow passes a *grobrechen* or coarse screen with six wings, one of which is in the sewage; when this becomes slightly clogged, an attendant turns it and removes the screenings. These wings are about 3 m. long. The fine screens are of 2-mm. piano wire with 2-mm. spacing, and are on large steel frames. There are six of these screens, three of which are sufficient for ordinary flows. The fine screens are cleaned by rotating arms which rake off all screenings, and are in turn cleaned by a scraper which removes the screenings to a continuous conveyor. The average quantity of screenings is 13 cu. m. per day (10 cu. m. between 8 A. M. and 9 P. M., and 3 cu. m. from 9 P. M. to 8 A. M.). The plant has been in operation 10 years, and costs about 40 000 Marks ($10 000) per year for operation and repairs. The screened sewage contains only ½% of sediment after standing 2 hours. To operate all screens requires only 6 h. p., which is furnished by a steam engine capable of producing 15 h. p. The screenings are piled in large concrete bins having under-drains, and are covered with *torf* and chalk to keep the odor at a minimum. The screenings sell in October for 1.50 Marks per 1 000 kg. (36 cents per ton). Population, 400 000. Sewered area, 25 000 acres.

Cologne.—The sewage is screened by 0.5 and 2.5-mm. screens, and these are cleaned by wire brushes which carry the screenings to an endless conveyor and thence to a car which removes them to concrete pits for storing, as at Düsseldorf. The screenings sell at 0.50 Mark (12 cents) for a 2-cu. m. wagon load, and 0.30 Mark (7 cents) for a 1-cu. m. load. The odor here was nil at the screens, but very bad at the compost piles. The screens remove about 15 cu. m. per day from 75 000 cu. m. of sewage. Population, 440 000. Future works are to be built with Reinsch-Wurl screens because of the greater accessibility of the whole screen and cleaning devices for repairs.

Mr. Whipple.

Wimbledon, England.—The screens consist of fixed bars, with engaging teeth to clean them, the latter being operated by motors. Similar screens are in use at Chester, Birmingham, Salford, Wakefield, and Huddersfield, at present, and differ widely from the Carshalton screen shown in this paper, inasmuch as the screen is fixed and the cleaning device movable, whereas the Carshalton screen itself moves and is cleaned at the top.

Rochdale, England.—The same general type of screen is in use in Rochdale as at Wimbledon, but the method of cleaning is slightly different and worthy of mention.

"The three screening and raking apparatus (Law's patent) are fixed in chambers 8 ft. wide and 6 ft. 9½ in. deep at the outlet end * * *. Each inclined screen is fitted with taper section steel bars 7 ft. 6 in. long, spaced ½ in. apart, the maximum sewage level being about 5 ft. The raking gear above the coping consists in each apparatus of a built-up steel framework * * * carrying a travelling-cleaning rake fitted with * * * malleable prongs. The rake is suspended by two vertical 'T'-section arms from a cross-bar on the chains, and is counterbalanced * * *. The ends of the rake are fitted with runner pulleys, working between cast-iron guides in front of the inclined screen. In working, the rake descends through the guides farthest from the screen, and ascends through the guides nearest to the screen, the prongs engaging in the spaces between the screen bars and removing the refuse therefrom. A vertical steel plate is fitted at the top of the screen to prevent the refuse falling from the rake, and, on the rake arriving at the highest point of travel, the refuse is automatically discharged by a cleaner, consisting of a set of vertical prongs in a cross-bearer, actuated from the detachable chains which carry the rake. At the junction of the 'up' and 'down' guides a hinged flap is fitted, to ensure the rake descending the guides farthest from the inclined screen."*

North Bierley, near Bradford, England.—Wool fiber and picric acid are the chief trade wastes in this locality, so a screen was designed to be as completely accessible as possible and still effectively remove the fibers. The screen consists of a perforated sheet of copper, about 7 ft. square and bent to form a half cylinder, along which the sewage flows. Revolving wire brushes pick up the lint and other solids and are in turn cleaned by a straight bar which passes over them when they reach the upper edge of the screen. This type of screen was adapted from the screens used in the mills near-by.

Rothwell Urban District Works, near Wakefield.—The use of a rapidly revolving disk screen at this plant, which receives a daily dry-weather flow of 54 000 gal. from 4 000 people, is chiefly to break up the solid matter before sending it to the trickling filter. This is probably the only plant of this type in existence. The sewage first

* Institute of Municipal and County Engrs., June 14th, 1913, by the courtesy of Mr. S. S. Platt, Borough Surveyor.

Mr. Whipple.

passes a bar screen with ½-in. openings, and then is pumped up to the disk screen, which revolves rapidly in a horizontal plane, allowing the liquid and most solids which are well broken up to pass through the ¼-in. holes and rejecting practically only mineral and other heavy solids which are not easily broken up. These are caught in a tray at one side and removed to be buried, as the volume is very small. It may be well to add that the trickling filter bed is chiefly composed of broken brick with a 2-in. top covering of 1-in. gravel.

Colehall, near Birmingham.—This is a rather good example of a trickling filter installation working well without screens. This plant was constructed some years ago, but within a year has come under the control of the Birmingham Corporation. The sewage is practically identical with that of Birmingham. The population served is about 60 000, and the flow is 2 400 000 gal. daily. The flow is directed through three settling basins in series, the heaviest material, chiefly mineral, settling out in the first and the finer in the latter basins. The basins are cleaned by a clam-shell bucket operated from a track at the side. The first basin is cleaned every 2 weeks, the second every 4 weeks and the third every 8 weeks. If a heavy storm occurs when the first basin needs cleaning, the material is simply flushed over into the next basin. At no time has there been any trouble with detritus being washed past the third basin. The results of the operation are: Suspended matter, raw sewage, 500 to 800 parts per million; influent to sprinklers, 50 to 120 parts per million; oxygen absorbed, raw sewage, 200 to 300 parts per million; influent to sprinklers, 50 to 90 parts per million.

The author does well to emphasize the need of greater system in keeping the results of operation of sewage screens and of weighting the results of samples on the basis of the corresponding volumes of sewage flow when the samples were collected. He might have added, also, the need of more frequent sampling.

In spite of the greatest care in devising and maintaining systems of sample collection and analysis, the results will be understood by only a few. There is need of a simpler and more tangible record of suspended matter than that which is used.

An excellent method of keeping such a record is that of filtering samples of water through cotton disks. A given volume of water, say 1 gal., is filtered through a disk of absorbent cotton, about 1 in. in diameter, specially prepared for the purpose. This is most conveniently done with a simple apparatus known as the "Wizard Sediment Tester" which is made by the Creamery Package Manufacturing Company, of Albany. The cotton disk, which is the filtering medium, is held between two supports of wire cloth in a cap attached to an ordinary glass milk bottle. The water to be filtered is placed in the bottle and allowed to flow out through the cotton disk. Filtration is hastened by increasing the pressure of the air within the bottle by the use of a simple air

compressor operated by a hand bulb. For samples of sewage, a much smaller quantity than 1 gal. is required. The cotton disk sediment record has the following advantages: Mr. Whipple.

1. It can be made very easily and quickly;
2. It can be made by the laborer and the office boy as well as by the engineer or chemist;
3. It is inexpensive;
4. The records are picturesque, and easily understood by every one;
5. The records are permanent;
6. The records may be conveniently mounted for preservation;
7. The records may be photographed;
8. A relatively large volume of water is tested; and
9. It is a valuable supplement to the regular water analysis.

C. A. JENNINGS,* Assoc. Am. Soc. C. E. (by letter).—Mr. Allen has compiled a mass of useful and interesting information and data on the subject of fine-screening of sewage. The writer has had much difficulty, in searching English publications, in finding very much reliable data on this subject. This paper will serve a very useful purpose. There is no doubt that in the United States fine screens have not received the attention they deserve. Whereas numerous experiments have been made on the various types of settling tanks, none has been made on the use of fine screens, so far as the writer is aware. Mr. Jennings.

The Jennings screen was mentioned by Mr. Allen as a recently patented type of band screen. This screen is handling successfully in Chicago a typical stock-yards sewage, which is rich in corn, straw, and hay, and cattle, hog, and sheep manure, and there is also present some human sewage. It comes from an area of some 30 acres, on which are live-stock pens, streets, buildings, etc. Formerly, the screen was cleansed by air under a pressure of about 45 lb., delivered through $\frac{3}{64}$-in. perforations in a $1\frac{1}{2}$-in. pipe. These holes became clogged with rust from the air pipe, and the high pressure of the air wore out the screens rapidly. This has been entirely remedied by supplying about 500 cu. ft. of air per min., under a pressure of $1\frac{1}{2}$ lb. per sq. in., through a slotted 3-in. pipe. The air is supplied by a positive blower driven by the same motor that drives the screen. This has overcome the objections to the high-pressure air, and, at the same time, has increased the efficiency of the screen. The data in Table 19 are from a forthcoming report of the Sanitary District of Chicago, dealing with the sewage problem at the Chicago Stock Yards. The writer is indebted to George M. Wisner, M. Am. Soc. C. E., Chief Engineer, and Langdon Pearse, M. Am. Soc. C. E., Division Engineer, for their use, the data having been collected under their direction.

* Chicago, Ill.

Mr. Jennings.

TABLE 19.—CRUDE SEWAGE.

Test No.	Rate of flow of sewage.	Gallons per square foot of screen exposed.	MOIST SCREENINGS.		DRY SCREENINGS.
			Pounds, per million gallons.	Percentage of moisture.	Pounds, per million gallons.
1.....	1 120 000	2.11	6 170	83.0	1 050
2.....	1 138 000	2.14	4 820	80.4	945
3.....	1 440 000	2.71	7 860	82.0	1 420
4.....	1 305 000	2.45	7 390	86.6	990
5.....	1 203 000	2.37	7 200	82.5	1 260
Average...	1 241 000	2.36	6 690	82.9	1 130

NOTE.—With screenings weighing 55 lb. per cu. ft., the volume of screenings varied from 3.2 to 5.3 cu. yd., and averaged 4.5 cu. yd. per million gallons of sewage screened.

Mr. Allen mentions the high moisture content of the screenings. This was due, at that time, and in the data in Table 19, to the method of constructing the screen frames of this first installation. Due to particles of corn, coal, gravel, etc., rolling down the screen, a 2 by 2 by $\frac{1}{4}$-in. angle-iron, with an outstanding leg pointing up on the lower side, was substituted for the $\frac{3}{4}$ by $\frac{1}{8}$-in. plate. This angle-iron retained the larger particles which formerly rolled down the screen, but it also retained considerable water until the frame reached the top of the incline where the blast of air blew off the screenings. This trouble has now been overcome by perforating the angle-iron with $\frac{1}{2}$-in. holes, so that the water drains out before the screen reaches the top of the incline. A number of tests made recently showed the average moisture content of the screenings to be 73.5%, as against a former average of 79 per cent. These wet screenings are easily handled with a shovel or pitchfork. They are dark green in color, and, while fresh, the odor is inoffensive. Table 20 gives typical analyses of the screenings.

TABLE 20.

Percentage of moisture.	CALCULATED TO DRY WEIGHT—PERCENTAGE.			
	Nitrogen.	Volatile matter.	Fixed matter.	Ether, soluble.
83.0	2.24	93.0	7.0	4.1
80.4	1.60	94.0	6.0	3.0

NOTE.—These data are from a forthcoming report of the Sanitary District of Chicago on the Stock Yards sewage problem.

On a recent installation, the percentage of moisture in the screenings has been reduced by reversing the angle-iron referred to, so that

Mr. Jennings.

it carries no water with it, the water draining through the screen immediately.

The writer is of the opinion that percentage-removal data mean little. Probably the technique of this determination differs in every laboratory. When one considers the immense quantity of sewage screened, the very small portion of this volume going to make up the composite sample, the small quantity of the composite sample used for the determination, and finally the size of the particles in suspension in the raw sewage, it is easy to see many chances for error in making this determination. The writer has seen a chemist use a 10-cu. cm. pipette to collect a sample of raw sewage to determine the suspended matter, in spite of the fact that very few of the particles in suspension could be sucked up through its tip. Not less than 40 or 50 cu. cm. should be used in making this test, and the sample should be collected in a graduate, in the top of which a funnel is placed. The bottle of sewage is shaken in an inverted position above the funnel and graduate, and the stopper or one's hand quickly withdrawn and sufficient sewage allowed to enter the graduate through the funnel. This method has been tested by the writer and found to give comparable results.

Sewage from about thirty-five packing houses enters Bubbly Creek, or the Stock Yards Slip, a branch of the Drainage Canal. This sewage is quite strong. It contains considerable fat and particles of skin and hair which are not intercepted in the catch-basins of the various packing houses. The Jennings screen is now handling a similar sewage in another city. At Chicago, this packing-house sewage receives no treatment other than the passage through catch-basins. It is with this problem that the Sanitary District of Chicago has experimented for about two years, and a report is now being prepared on the results of this work. It seems to the writer that here is an excellent field for fine-screening. The water from the Drainage Canal is not used for domestic consumption, and, furthermore, the particles that can be removed by fine screens are those which would settle to the bottom of the canal to a great extent and form deposits. In this way much of the small quantity of dissolved oxygen in the canal would be used up. It is desirable to remove this matter in suspension, and a cheap, effective, and quick method of doing so is by fine-screening.

Other fields for fine screens have appeared in manufacturing plants where the problem is either to recover something in suspension which has value, or to prevent something in suspension, which has no value, from being discharged into a stream or other body of water. The more the writer has gone into this subject, the more he is convinced that fine-screening of sewage has been overlooked to a large extent, and that there are many places where its application is as good as, or, in some instances, even preferable to, tank treatment.

Messrs. Franze and Schaefer.

MESSRS. G. FRANZE* AND — SCHAEFER† (by letter).—The author's painstaking work forms an important contribution in settling the question of the importance of screening installations in the field of sewage clarification. While acknowledging the correctness of Mr. Allen's deductions and conclusions, the writers beg to present some additional observations founded on their experience.

In considering a plant about to be installed, one should provide for the most complete treatment that may be demanded, if he wishes to satisfy the variety of requirements that may arise eventually for the cleanliness of the stream. A plant, therefore, should be planned and provided from the beginning with everything which later may be necessary for the kind of treatment which has proved satisfactory in all cases. Its development in accordance with the more complete demands of the future can then be temporarily postponed, provided the conditions are such as to make this advisable. In such cases, the first installation of the plant should provide for mechanical cleansing by screens (bars, sieves, grids, etc.).

This procedure is to be preferred under the following circumstances:

(1).—As an independent and separate arrangement for the removal of suspended matter greater than a given size where the stream to which the effluent passes is large, thereby providing ample dilution, and where there are no communities below which require the use of the water; and also where there are æsthetic reasons for preventing the fouling of the shores.

Such independent arrangements, however, have no influence on the removal of dissolved impurities. These are disposed of by the biological purifying agencies contained in the stream itself, as long as the volume of sewage remains within certain limits relative to the self-cleansing ability of the stream.

(2).—As a preliminary clarification plant in connection with other processes for the further removal of the finest suspended matter. In this case screens form also an independent and necessary feature:

(*a*) During periods of flood in the stream;

(*b*) Without affecting unfavorably further clarification;

(*c*) Without preventing the subsequent treatment of the sludge by machinery.

(3).—As a protection to pumps in systems of low-level sewers.

The conditions affecting plants mentioned under (1), (2), and (3), depend further on the kind and composition of the domestic and factory wastes. The best and most efficient results are with fresh sewage. The most unfavorable are with stale sewage, where the im-

* Stadtbaurat, Frankfort, Germany.

† Stadtbaumeister, Frankfort, Germany.

purities reach the plant in a finely broken up and decomposed condition. The most important advantages in mechanical treatment are the following: Messrs. Franze and Schaefer.

(1).—The product contains only about 75% of moisture and is, therefore, in its firm condition, capable of transportation. The quantity removed, if carried to tanks or other arrangements, would increase the quantity of sludge by from 10 to 15 per cent.

(2).—The fertilizing value of the material is greater, thus paying for its carriage to a greater distance.

(3).—The removal of coarse and clogging material renders possible an unobjectionable and certain removal of sludge from the tanks which, in some cases, must be provided with complicated pipe systems for its removal either by suction or pressure.

(4).—This also holds good in the further mechanical treatment of the sludge.

(5).—The simple and automatic machinery requires only a small sum for service and power.

With regard to the agricultural use of material removed by mechanical devices, it was formerly given to neighboring farmers. After experiments made at Frankfort, Germany, however, it is now possible to dry the product by the chimney gases of the refuse incinerator so completely, in a drying drum, that the heat developed in burning can be utilized for electric power, or the material can be used on farm lands as poudrette.

The choice between the successful mechanical plants now known—which may be divided into two groups, fixed and movable—should be made in each case only after a thorough study of local conditions as well as of the character of the sewage and the stream into which it is discharged.

GEORGE W. FULLER,* M. AM. SOC. C. E. (by letter).—Mr. Allen has written a good paper on a subject about which practical knowledge in the United States falls far behind that which is available in Europe. Undoubtedly, his conclusion is correct, that fine screens for sewage clarification are entitled to more consideration than they have generally received hitherto in America. Mr. Fuller.

As a general proposition, it may be safely stated that fine screens have their legitimate field of usefulness where the clarification effected by them can be accomplished at less cost than by other available methods, when due consideration is given to capital charges and depreciation, as well as to ordinary operating expenses and current maintenance. In some places where the total cost of screens might be somewhat greater than that of settling tanks, the convenience may justify their use.

* New York City.

Mr. Fuller.

Fine screens are most serviceable in cases where clarification alone or in combination with sterilization is sufficient treatment to give to the sewage. Where settling tanks are used, fine screens do not seem to be of sufficient aid to justify their cost. Perhaps exceptions may be found in instances where some by-products of value are to be found.

In connection with filters of various types, fine screens do not seem to have established themselves as of much practical aid if exception be made of cases like Baltimore, where gas ebullition lifts much sludge at times from the single-story tanks on to the filters. The experience of Brockton is of much interest, and it would be helpful to know how expenditures for fine screens there would compare with what could be accomplished by modern settling tanks, in lessening the load on the sand filters.

Last spring, the writer designed a sewage treatment plant at Daytona, Fla., in which Riensch-Wurl screens (with a width of opening of $\frac{1}{12}$ in.) and sterilization afford the only treatment before the dispersion of the sewage in the Halifax River not far distant from shellfish layings. It was concluded that these fine screens would give sufficient clarification and that the cost would be materially less than for settling tanks for a city where quicksand underlies practically the whole area, with its upper surface from 6 to 12 ft. below the surface of the ground and extending to depths of some 30 to 40 ft.

Mr. Allen's paper has much value for reference, on account of the European data which it presents. The writer believes, however, that actual experience with fine screens in the United States is likely to show a smaller removal of suspended matter than would be inferred from statements in the paper. Thus, at Reading, Pa., there is quoted a removal of dry matter equal to 90 parts per million, whereas, for several years, the writer's studies indicated that, on a basis of daily averages, this removal rarely if ever exceeded 30 parts per million. Without doubt, the comparatively dilute American sewages cannot be clarified with the same relative efficiency by fine screens as the concentrated sewages of Europe. As the sewage becomes comminuted, through age and mechanical attrition, incident to flowing through long outfall sewers, the efficiency of fine screens will become less.

Generally speaking, fine screens have not been built strongly enough, either in the United States or in the earlier installations in Europe, to do their work satisfactorily without more or less overhauling and reinforcing. Without such heavier construction, the periods of interruption and the cost of attendance become relatively great. There should be due allowance for this factor in making a preliminary estimate of cost.

Notwithstanding the foregoing comments as to lessened efficiency, as compared with the author's statements, and the likelihood of greater cost, the writer believes firmly that in the future fine screens will play

a prominent part in solving many problems of sewage treatment in America. Mr. Fuller.

J. X. COHEN,* JUN. AM. SOC. C. E. (by letter).—The author deserves credit for the presentation of data (undoubtedly collected with much effort) which enrich the meager American literature on sewage screening. He has brought to the attention of American engineers a process of sewage treatment which merits more attention than it has received as yet in the United States. Mr. Cohen.

Most sewage screens in the United States are of the crude bar type, and although they serve their intended purpose more or less effectively, there are without doubt a number of plants where improved screens, if planned with the painstaking care shown in most of the designs presented in the paper, would give better results.

The success of the mechanical screens discussed by the author, however, will become possible in America only when more of our municipalities come to hold enlightened views regarding the necessity for skillful operation and scientific supervision in sewage treatment works. It will be of little avail to install an expensive screen of high efficiency, and then allow its control to be vested in an operator of the type so usual in numerous American sewage disposal works. Whereas the methods and structures now in use are capable of more abuse in practice, without great deterioration in the quality of the effluent, than are mechanical screens, and in consideration of the present attitude of many public officials, that sewage disposal works are necessary evils, frequently forced on them by Court orders, which must be tolerated, but to which as little attention as possible should be given, sanitary engineers who realize the conditions fully, will hesitate to recommend the installation of automatic screening machinery.

On the other hand, it may be that the installation of such screens in progressive communities, where problems of municipal management of public works are being solved, not from the viewpoint of political exigency, but from that of scientific reliability, will present concrete object lessons in economical municipal management that in time will be learned. Without this recognition of the importance and the vital necessity for reliable sewage works operation, however, much of the effort and expense involved in the design and installation of high-efficiency, sewage-screening machinery will be lost.

The writer is of the opinion that, in the design of sewage screens, the convenience of the attendant has not always been kept in mind. This opinion is based on an experience of about 8 years, and refers in particular to small plants. The result of this lack of prevision is that screens are either improperly cared for, neglected, or are completely removed from the sewage flow.

* New York City.

Mr. Cohen.

As it is a well-known fact that many small sewage disposal works are poorly conducted and therefore produce effluents which are not wholly satisfactory, it should be the duty of the designing engineer to arrange the various parts of the plant so that in their operation the attendant, at all times, will be as free as possible from arduous labor in awkward positions. As an instance of the apparent failure to keep in mind during design the practical operation of a screen, there may be mentioned a small disposal works near New York City where the operator has found the task of cleaning the screen so difficult, because of its position, that it has been neglected for a long time, with the natural result that it clogged and the sewage on its way to the pumps overflowed the screen. Thus far, it is not known that this has caused any trouble at the pumps, but, of course, deposits have accumulated above the screen, with the accompanying nuisance. As this particular screen-chamber is covered, it will be some time, perhaps, before the odors of decomposition become sufficiently obnoxious to force the removal of the deposits.

In another small plant, the basket-bar screen is too heavy and cumbersome for the lone operator to handle conveniently, and the result has been the withdrawal of the screen from the well. The sewage now flows unscreened and uninterrupted to the pumps, thereby endangering their safe and continuous operation. Such practices do not enhance the respect of the operator for the engineer, nor redound to the credit of the latter.

There is a feature of fine sewage screening that will be of service to its development in America, which deserves considerable attention. Centrifugal pumps are now used extensively in pumping sewage, and in most recent designs other types have not been given equal consideration. Fine screens will eliminate the grosser solids found in coarse screened sewage, and the manufacturers of centrifugal pumps will be enabled to design impellers and pump casings which will allow the pumps to attain higher efficiencies than are now feasible. For large flows, the saving in the cost of pumping thus obtained will be a factor which should have considerable and favorable influence on the decision concerning the use of mechanical screens.

Mechanically operated fine screens in large plants probably receive the skilled attention which they require, but in smaller plants, where the quality of the effluent may be equally important, if not more so, such screens may not always receive as good attention. Hence, it behooves engineers to give sufficient study to the design of sewage screens, whether of the simple stationary bar type or the more complex mechanical type, in order that, under practical operating conditions, they may receive more than sporadic attention. Such attention, or rather lack of attention, forces the other parts of the disposal works to exercise functions for which they are not designed, with the con-

sequent lowering of their efficiency. By presenting to the Society data which indicate how other engineers are ingeniously working out the problems of sewage screening, the author has made a noteworthy contribution which should stimulate other members to equal endeavors. Mr. Cohen.

F. T. ROBSON,* Assoc. M. AM. SOC. C. E. (by letter).—While engaged in the design of a sewage disposal system in Southern California, the writer heard of the great difficulty that The Anaheim Sugar Company was having in disposing of its waste water which carried a large percentage of sugar-beet waste. The factory was in a thickly settled, highly developed farming district containing many small cities, and at such a distance from the ocean as to make it an economic impossibility to discharge the waste water there. It might have been delivered directly to the citrus orchards immediately adjoining, or into a ditch for irrigating lands at a greater distance. Most of the farmers refused to use the water, as the factory operates for the entire 24 hours of the day during a "campaign", and night irrigation, as well as painstaking attention to cover or plow under the large quantity of suspended matter, would thus be necessary. Mr. Robson.

The factory had been completed and put in operation in 1911, and the campaign of 1913 was fast approaching when the writer was asked to report on the problem. In 1911 the wastes were discharged in an artificial 55-acre lagoon near the plant, and readily decomposed under anærobic action, producing much hydrogen sulphide. Many serious complaints from near-by residents resulted. In 1912 the wastes were discharged into an irrigation ditch, but the large quantity of organic suspended matter caused difficulty similar to that in the previous year. Complaint was made to the State Board of Health, so, in 1913, the company was compelled to abate the nuisance or close the factory. It was essential that something be done at once, for the time was short.

In local parlance the word "campaign", used in connection with a sugar factory, means the period from the time when the first beets are received, or the factory is started, until the last beet has been cut up and the factory closed. During this time the factory runs 24 hours per day and a shutdown is a serious matter. All energies during the "closed" period are devoted to putting everything in such shape as to minimize the chance of a breakdown.

After careful study the only available methods of solving the problem seemed to be:

(1) Fine screening;
(2) Sedimentation.

The dearth of information regarding recent installations of fine-screening devices, their cost, operating difficulties, etc., was astonishing.

*San Francisco, Cal.

Mr. Robson.

For this reason Mr. Allen's paper is especially valuable, and should be of wide interest, for fine screening is available as a method of sewage disposal in a large number of cases. He has collected in one paper far more information, as to design and operation, than was found by the writer in a number of authorities consulted.

On investigating this local matter, many aspects differing from the usual sewage disposal problem were found, and Charles Gilman Hyde, M. Am. Soc. C. E., Professor of Sanitary Engineering, University of California, was asked to assist. His report was very detailed and comprehensive, and of great value, because it was the first time in California and probably in America that the disposal of beet sugar factory wastes had been studied scientifically. Tables 21, 22, etc., are taken from Mr. Hyde's report to the writer.

TABLE 21.—CHEMICAL ANALYSIS OF ROUGHLY SCREENED BEET SUGAR WASTE.

	Determinations.	Parts per Million.
Solid matters	Total	2568.0
	Mineral	1521.6
	Organic and volatile	1066.4
Suspended matters	Total	1891.2
	Mineral	1208.0
	Organic and volatile	683.2
Dissolved matters	Total	696.8
	Mineral	313.6
	Organic and volatile	383.2
Nitrogen (N) as	Organic nitrogen	7.14
	Free ammonia	5.60
	Albuminoid ammonia	1.80
	Nitrites	0.19
	Nitrates	0.22
	Total	13.15
Oxygen consumed (O)	"Absolute"	1985.
	5 min. at 100° cent.	496.
	20 min. at 80° cent.	198.50
Sulphates (SO_3)	Total (dissolved)	50.60
Chlorine (Cl)	Total (dissolved)	40.00
Phosphoric acid (P_2O_5)	Total (dissolved)	Trace.
Potash (K_2O)	Total (dissolved)	10.05
Soda (Na_2O)	Total (dissolved)	43.50

As far as known, this installation is the first in which sugar factory waste has been treated by fine screening; it is also the first installation of a screening device of any kind in California. A brief description may be of interest.

Investigations preliminary to design showed that the volume of waste requiring treatment was about 2 200 000 gal. daily during the campaign (approximately from August 1st to November 1st).

Mr. Robson.

General Character of Waste.—The waste consisted of discolored water heavily loaded with suspended matter most of which was heavier than water—some lighter; it was largely sand, silt, clay, beet tops, roots, cuttings, etc., the impurities from beets or unpurified sugar, and the sewage from 200 employees.

Chemical Analysis of Waste.—The result of a chemical analysis of roughly screened waste, made at the University of California, is given in Table 21; and from this it follows that the suspended solids were equivalent to about 15 800 lb. per million gallons.

Analysis of Water.—The mineral composition of the water carrying the waste is shown by Table 22.

TABLE 22.—ANALYSIS OF WATER CARRYING WASTE.

Determinations.		Parts per Million.
Total solid matters	Total	397.0
	Mineral	357.0
	Organic and volatile	40.0
Suspended matters	Total	0.0
Dissolved matters	Total	397.0
	Mineral	357.0
	Organic and volatile	40.0
Sulphates (SO_4)	Total (dissolved)	22.2
Chlorine (Cl)	Total (dissolved)	34.5
Alkalinity due to sodium carbonate		6.4
Incrusting solids:		
Calcium and magnesium carbonate, etc., chiefly small		244.0
Calcium sulphate (Gypsum)		
Silica (SiO_2)		10.0

Volume of Suspended Matter.—(*1*) *By Imhoff Graduates.*—

Time of subsidence.	Average volume.
1 min	6.3 cu. cm.
2 "	6.9 "
3 "	7.1 "
4 "	7.2 "
5 "	7.3 "
10 "	7.4 "
15 "	7.6 "

This is equivalent to 37.8 cu. yd. per million gallons, or, for the daily flow of 2 200 000 gal., a total of 83.2 cu. yd. of wet sludge having a moisture content of about 95%, giving a total dry weight of 3 170 lb. per million gallons, or 34.87 tons per day after 15 min. sedimentation. Computing the total suspended solids as 15 800 lb. per million gallons, the quantity capable of settling in 15 min. would be about 20 per cent.

Mr. Robson.

For this reason Mr. Allen's paper is especially valuable, and should be of wide interest, for fine screening is available as a method of sewage disposal in a large number of cases. He has collected in one paper far more information, as to design and operation, than was found by the writer in a number of authorities consulted.

On investigating this local matter, many aspects differing from the usual sewage disposal problem were found, and Charles Gilman Hyde, M. Am. Soc. C. E., Professor of Sanitary Engineering, University of California, was asked to assist. His report was very detailed and comprehensive, and of great value, because it was the first time in California and probably in America that the disposal of beet sugar factory wastes had been studied scientifically. Tables 21, 22, etc., are taken from Mr. Hyde's report to the writer.

Silica (SiO_2)		10.0

Volume of Suspended Matter.—(1) By Imhoff Graduates.—

Time of subsidence.	Average volume.
1 min.	6.3 cu. cm.
2 "	6.9 "
3 "	7.1 "
4 "	7.2 "
5 "	7.3 "
10 "	7.4 "
15 "	7.6 "

This is equivalent to 37.8 cu. yd. per million gallons, or, for the daily flow of 2 200 000 gal., a total of 83.2 cu. yd. of wet sludge having a moisture content of about 95%, giving a total dry weight of 3 170 lb. per million gallons, or 34.87 tons per day after 15 min. sedimentation. Computing the total suspended solids as 15 800 lb. per million gallons, the quantity capable of settling in 15 min. would be about 20 per cent.

Mr. Robson.

Volume of Suspended Matter.—(2) By Screening.—Brass sand-analysis sieves, of 40 and 100 mesh, in tandem, gave the following results:

On the 40-mesh screen, from 17 240 cu. cm. of waste, 71.3 grammes wet, or 3.7 grammes dry, were caught; or, on the basis of 15 800 lb. per million gallons, the percentage was 11.3%, or an estimated quantity of 46.6 cu. yd. of wet material per day.

On the 100-mesh screen, 11.4 grammes wet, or 0.9 grammes dry, were retained; or, on the basis previously given, about 14.0% was retained with both screens.

Although these percentages appear to be low, the material removed represents that portion of the waste matter that caused the trouble by decomposition.

Location of Plant.—The factory is on an old river bed or channel of sand, which is very fine in the top layers, but grows coarser with depth. Tests showed the perfect feasibility of intermittent filtration, after the top layers of sand were removed. It was thus determined that some process of preliminary treatment followed by sand filtration must be used. The following figures give an idea of the estimated cost of the complete plant of the two types best adapted to the work:

	Cost of construction.	Annual operating expenses.
Fine screening and intermittent sand filtration	$32 500	$6 600
Sedimentation in Imhoff tanks and intermittent sand filtration	84 500	8 900

These annual operating costs include interest on the investment at 6%, depreciation, maintenance, labor, and power costs.

The fine-screening method, with a battery of two screens, having been recommended, plans were prepared. The company, however, expressed some doubts as to the success of the plant, and decided to invest in only one screen for the present, though space was provided in the screen-house for two.

A Weand rotary screen of the Atlanta type, furnished by the Merritt Hydraulics Company, was put in. It is cylindrical, 10 ft. long, 8 ft. in diameter at the inlet and 6 ft. at the outlet, and is covered with a 40-mesh screen. It is chain-driven from a 5-h.p. motor at a speed of 10 rev. per min. The lower half of the inlet end is closed, but there is an opening for the supply pipe. The water entering the screen filters through the bottom portion, and the suspended matter is carried by worm plates to the outlet and deposited by a chute in an iron push-car with a perforated bottom. The screen is kept clean by water jets or nozzles.

Mr. Robson.

The screenings are dumped on an open compost heap, where they gradually dry, with no disagreeable odor. When dry, the compost is used by the farmers as a fertilizer.

The screened water passes from the screen to a sump and thence by gravity to thirty-six filter beds, each 100 by 200 ft., or a gross area of 26 acres. These beds are covered once in 24 hours with about 4 in. of the screened water. They perform their function satisfactorily, and no odor is apparent. The plant is now going through the second campaign, and the results have been very successful.

The screen itself, however, has given a great deal of trouble. It was doubtless the first one manufactured by the present makers and, at the time of purchase, they had not fully completed their arrangements with Mr. Weand's heirs. The mechanical details of the screen were very poor, and for this reason the operating delays were numerous. In fact, the screen was almost completely rebuilt during the season. Notwithstanding annoyances and delays of this nature, the company has been well satisfied, and the total capital expense for the complete plant, to date, has been about $30 000.

The cheapest alternate method of disposal would doubtless have cost three times as much, could not have been finished in time for the 1912 season, and would have been more expensive to operate.

The wet sludge or screened material has been found to contain about 92% of moisture and to weigh about 45 lb. per cu. ft., as it comes from the screen, without compacting. The quantity of sludge varies largely with local conditions in the factory, but the volume per day or week checks closely with that estimated.

Mr. Potter.

ALEXANDER POTTER,* ASSOC. M. AM. SOC. C. E.—The speaker would like to add a tribute to the thoroughness with which the author has presented this subject. Although experience with fine sewage screens in the United States is limited, this is not true of Europe where fine screening is in more general use. This is especially true in Germany, where, since 1903, the Government has sanctioned the discharge, into large bodies of water, of sewage from which all suspended matter more than 3 mm. in diameter has been removed.

The principal contributing causes for the relatively small use of fine screens in America, as compared with their use in Europe, appear to the speaker to be the following:

First.—The failure of competent authority to establish reasonable regulations as to what would constitute adequate treatment under all conditions. There has been too great a tendency to permit the gross pollution of waters by sewage for much longer periods than are desirable, and these periods have been lengthened unconscionably by the insistence of too many of the State Boards of Health on standards

* New York City.

Mr. Potter.

of purification which are too high. Consequently, simple processes for removing the grosser pollution have not been received with favor.

Second.—European experience with the cost of operation and maintenance of fine screens indicates that these items will be exceeded by fully 100% in American practice.

Third.—As most purification works which are projected demand more than one step in the process, fine screens have not seemed capable, for a given cost, of producing results as satisfactory as those obtained with settling tanks of the latest design.

The percentage of suspended matter in the sewage removed by fine screening, as compared with settling, is not a true measure of the relative efficiencies. For the same percentage of suspended matter removed, the screened liquid is far inferior to the settled effluent. The truth of this assertion is amply verified by an examination of Table 4. According to this table the suspended solids before screening amount to 2 112.8, and after screening they amount to 785.2—a reduction of 62.9%; whereas, on the other hand, the residue of the filtered liquid after evaporation has been increased from 1 237.2 to 1 260.4. The speaker is of the opinion that the author's statement, that the organic matter in solution has been increased only 1.9%, is in error. From both quantities should be deducted the total stable solids in solution, these solids being the same in each case. Deducting these, the relation between the organic impurities in solution before and after screening will show a much greater percentage of increase than that stated by the author.

It would seem that in the fine-screening process a portion of the solid matter is converted into colloidal matter in its passage through the screen. As this colloidal matter will pass through filter paper, the screens are credited with a greater percentage of removal than they are entitled to. The transformation of a certain portion of the suspended matter in the sewage into colloids during the process of screening increases the organic impurities in the liquid to a very material extent.

To bear out this statement, the speaker quotes from Mr. John D. Watson's report of 1912 in discussing results obtained at Ashold and Sutton. At this plant, the sewage passes through grit-chambers and receives a preliminary treatment by passing through two Carshalton screens. As to the efficiency of these screens, Mr. Watson says:

"Some time ago one of the Carshalton screens required renewal. This, however, I decided not to do owing to the discovery that the sewage contained more organic impurities *after* it was screened than it did before, thus adding unnecessarily to the work of the bacteria beds. Mr. O'Shaughnessy's report stated that 'Fæcal matter forms a colloidal solution when agitated with water; and the increase in the oxygen-absorbed figure, together with the increase in the colloidal matter present in the sewage liquor after passing the screen, showed con-

clusively the objectionable action of the screen'. The object of eliminating solids is to reduce the strength of the liquid, but to brush particles of fæces over the perforations of the screen and afterwards to force sewage through those perforations must tend to defeat the object in view. The truth of this forced itself upon me in viewing what is perhaps the most complete and elaborate screen I have ever seen, viz., that by Riensch at Dresden." Mr. Potter.

George M. Wisner, M. Am. Soc. C. E., discovered the same phenomena at the Thirty-ninth Street testing station in Chicago, as mentioned in his report of 1911 on "Sewage Disposal for the Sanitary District of Chicago".

It is the speaker's opinion, however, that where dependence for sewage disposal must be placed chiefly on dilution, there is a wide field for fine screening, for in that case the object to be attained is principally the removal of the rather large particles of suspended matter.

Where a high degree of purification is sought, the use of fine screens is of doubtful value. A modern settling tank will give better results and at less cost for a given degree of purification. A settled liquid also is superior to a screened liquid for subsequent biological treatment in filters. Furthermore, a settling tank can handle septic sewage or a sewage in which the suspended matter has become comminuted by pumping or otherwise.

Again, the storing of large quantities of screenings must necessarily be more objectionable than the storing of the digested sludge of a modern settling tank. Not only is the volume of this digested sludge less, but it is also of a less objectionable character.

Settling tanks have a further advantage over fine screens, in the speaker's opinion, in that with them it is possible to omit entirely the use of sludge beds, especially when settling and sterilization provide adequate purification. This can be done by creating a mechanical circulation through the settling tank. The suction pipe for this circulation system should extend down into the digested sludge and the sludge should be raised to a weir box a few inches above the water surface in the settling basin. It should be provided with an adjustable weir to regulate the discharge of digested sludge into the effluent in the proportion that such sludge bears to the volume of sewage flow. The remainder of the digested sludge thus circulated should be returned to the influent pipe, and, as it has a greater specific gravity than the fresh sewage, it will tend to entrain the suspended matter in such sewage, thus resulting in a higher degree of settling in the upper compartment of the tank. The continuous and uniform discharge of digested sludge retains at all times the maximum effective capacity of the sludge digestion chamber and prevents any sudden disturbance in its contents.

Mr. Potter.

The direct discharge of digested sludge, uniformly and continuously, into a body of water with the effluent is unobjectionable from a sanitary standpoint, and will cause less shoaling in the stream than the silt transported in storm-water sewers.

The speaker does not desire to convey the impression that there is no place where fine screens might be given preference. There are many instances, especially when the sewage contains certain trade wastes, whereby the preliminary process of screening—oftentimes of fine screening—is of great value to the subsequent treatment.

In reference to the nuisance created by the composting of large quantities of solid matter removed from fresh sewage, the speaker noted an absence of seriously offensive conditions at the storage yards. At Dresden a great number of chickens had free run over these piles. When the screens were first put into operation, they attracted great numbers of flies during the summer, but after the introduction of the chickens there was a marked absence of flies. No one around the plant had any hesitancy about eating the eggs or the poultry raised on this diet.

Concerning the cost of operation and maintenance of fine screens, the author's data, based on German practice, must be modified, of course, to adapt it to American conditions. The compensation of German labor is less than half that in the United States. As a rule, two shifts are employed in European cities, and three shifts would be necessary in America. Furthermore, it has been the speaker's experience that, as a general rule, the attention given to such plants in Germany cannot be secured in America at any price. It is hoped that this will not always be so. As a result of neglect in attendance, unsatisfactory results are only too often obtained, for which the machinery is blamed.

Screens may be justified because screenings are better fitted as a base for fertilizers than digested sludge. At Dresden, it is proposed to put in a plant for the utilization of the screenings in this way. No less an authority than Mr. John D. Watson has recently reversed himself as to the value of sludge as a base for fertilizers.

In conclusion, the speaker desires to raise this point for discussion: has the action of the German Government in permitting the discharge of settled or screened sewage into the streams of the country been justified? The speaker believes that it has. It has brought about an immediate improvement in all rivers. It has rendered possible the solution of problems otherwise impossible because of the great expense involved in more complete processes.

It is true, of course, that in cities like Birmingham, England, where the sewage flow exceeds the stream flow, more perfect purification is mandatory, but cities thus situated are the exception, especially in America.

Mr. Gregory.

CHARLES E. GREGORY,* ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Allen's paper supplies the Profession with many necessary data concerning the use of fine screens for the treatment of sewage. In the writer's opinion there is a very extensive field for such screens or other devices which will remove a considerable portion of the suspended solids from sewage which is to be discharged into harbors or rivers having sufficient volume of flow to dilute it materially. The best fine screens undoubtedly remove from fresh sewage a very considerable quantity of materials which are most potent in producing nuisances.

It has been the writer's experience, in most cases where he has had to examine and correct conditions which have given rise to complaints of local nuisance along the water-front of the New York Harbor, that the materials directly causing the nuisance are such as would have been removed by one of the better fine screens. River or harbor waters are capable of digesting without nuisance much greater quantities of sewage from which the coarser and heavier suspended solids have been removed than would be indicated by a comparison of the quantity removed with the total organic matter.

The prevention of the accumulation of material deposits of sewage silt by fine screening or sedimentation has prevented nuisances in practically every case where it has been tried. Large quantities of screened sewage from Dresden and Hamburg are discharged from submerged outlets directly into rivers where the dilution is not great, and apparently the discharge is without detrimental effects. London and Glasgow discharge enormous volumes of effluent, which has been treated by chemical precipitation only, into relatively small streams in which the net outward flow is exceedingly small. All the sewage from London is discharged into the Thames at two points, one on each side of the river, within a relatively short distance from each other. The enormous quantities of organic matter thus discharged reduce the dissolved oxygen content of the river to a very low point in the immediate vicinity of the outfalls, but the river water purifies itself and regains its dissolved oxygen very rapidly, both up stream and down stream from the outfall points. It is reported that the river water is practically as pure 20 miles down stream from the Crossness outfall as it is above London where it is taken for water-supply purposes. Many other instances might be cited to prove conclusively the enormous digestive capacity of waters where the heavier suspended solids have been removed from the sewage.

Recent full-sized experiments in Essen, Germany, have indicated, however, that two-story sedimentation tanks, with retention periods as short as 20 min., will remove from certain sewages about 90% of the matters removable in this way. If it is found that the reten-

* Mt. Kisco, N. Y.

Mr. Gregory.

tion periods for a sewage are short, and if suitable space and location are available, a short-time sedimentation tank will prove considerably more effective and less expensive than a fine screen for removing the suspended matters which have a maximum nuisance-producing effect if allowed to remain. Each particular case, however, will have to be studied and decided on its merits, taking into account:

First.—The nature of the sewage;
Second.—Available space;
Third.—Physical character of the site;
Fourth.—Cost of land;
Fifth.—Relative facility for removing sludge or screenings without nuisance; and
Sixth.—Purity of river or harbor waters required.

Either fine screens or sedimentation tanks may become offensive and objectionable when not properly cared for. The daily removal of screenings is necessary and, if neglected, may cause serious objections in a residential neighborhood.

The lower standards of purity for rivers and harbors, which have been adopted by Germany during the last decade, when compared with corresponding standards established in England, France, and America, during the same period, seem to the writer to have been fully justified by experience, and their practice, therefore, merits adoption by the various authorities of the United States where conditions are similar.

MEMOIRS OF DECEASED MEMBERS

NOTE.—Memoirs will be reproduced in the volumes of *Transactions*. Any information which will amplify the records as here printed, or correct any errors, should be forwarded to the Secretary prior to the final publication.

WILLIAM RICHARDSON BELKNAP, F. Am. Soc. C. E.*

DIED JUNE 2D, 1914.

WILLIAM RICHARDSON BELKNAP, the son of William Burke and Mary (Richardson) Belknap, was born in Louisville, Ky., on March 28th, 1849. He received his early education in the schools of that city, and was prepared for college at the Louisville High School. He then entered the Sheffield Scientific School of Yale University for the select course, and was graduated in the Class of 1869. While at Sheffield, he was a member of Berzelius, captain of the Undine Boat Club, and, in 1869, a member of the *Lit* Board.

After a year's post-graduate course in biology at Yale, Mr. Belknap returned to Louisville, and for three years worked with his father who was in the hardware business there. Subsequently, he spent another year in study in Germany.

On his return to Louisville, he took over his father's business. which at that time was conducted as W. B. Belknap and Company and consisted of one small store dealing almost exclusively in blacksmiths' supplies. Under his management the business grew into the concern known as the Belknap Hardware and Manufacturing Company, employing about 1 000 men, and having representatives in all parts of the United States. Thus, the narrow blacksmith line was broadened out until a description of the Company's manufactures filled a catalogue containing nearly 100 000 items. The present plant consists of modern warehouses with floor space of more than 24 acres and railroad side tracks accommodating 20 freight cars at a time.

In the spring of 1910, Mr. Belknap retired as President of the Company, after having held that office for nearly 30 years. He continued, however, as Chairman of the Board of Directors until his death on June 2d, 1914, following a general breakdown. In his business career he had always kept before himself and his employees the principles advocated by the efficiency engineers of the present day, namely, the elimination of all waste as well as of all waste movements, and he had built up one of the largest businesses in the South from very small beginnings.

Mr. Belknap was a Trustee of Berea College and was active in the support of the Tuskegee and Lincoln Institutes. He was a staunch

* Memoir prepared by the Secretary from information supplied by William B. Belknap, Esq.

supporter of the Kentucky Yale Alumni Association and the Kentucky Scholarship Fund, and was the founder of the William R. Belknap Prizes for excellence in geology and biology in the Sheffield Scientific School.

He was a Director of the Associated Charities of Louisville for nearly 20 years. He was also actively interested in both the Young Men's and Young Women's Christian Associations, and had served as an Elder of the Warren Memorial Presbyterian Church.

Mr. Belknap was for several years a Director of the Louisville Board of Trade, and had served on the Board of Directors of the Southern Exposition. He was one of the founders of the Salmagundi Club of Louisville, a member of the Country Club, and an Honorary Life Member of the Commercial Club, both of that city.

On December 2d, 1874, he was married to Alice Trumbull Silliman, daughter of Professor Benjamin Silliman, Jr., of Yale University. Mrs. Belknap died in November, 1890, and on February 21st, 1894, he was married to Miss Juliet Rathbone Davison, of Louisville, Ky. He is survived by one son and four daughters.

Mr. Belknap was elected a Fellow of the American Society of Civil Engineers on May 28th, 1872.

THE WATER-PROOFING OF SOLID STEEL-FLOOR RAILROAD BRIDGES.

By Samuel Tobias Wagner, M. Am. Soc. C. E.

To be Presented January 6th, 1915.

Synopsis.

The object of this paper is to submit a specification for the design, materials, and manner of application of the water-proofing of railroad bridges with solid steel floors.

Present practice in bridge construction of this type differs so much among engineers, as to design and materials used, that it is hoped that the discussion from those who have had experience with work of this class will be of value in determining on more uniform practice in a detail of modern bridge construction which is yearly commanding more attention.

The specifications, as presented, have been the outgrowth of about eight years' experience with structures of this class, and with a number of kinds of materials and design. Up to the present time, the specifications which have been used have been tentative, and based on the best information which could be obtained. It seems, however, that there are certain principles—more or less fixed—which may be lost sight of by the inexperienced designer, and the chief object in preparing this paper is to state specifically what they are believed to be, with the hope that the discussion will either refute or approve them.

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

The specifications are not intended, in any way, to cover the design of the structural work, but to call attention to those details which should be borne in mind by the designer when engaged on a structure, of the type under consideration, which has to be water-proofed. It is believed to be of great importance that the structural designer shall have in mind the fact that the water-proofing plays an important part in the details, and that it should be co-ordinated with the design as he proceeds.

Six Appendices are attached to this paper, for the purpose of adding such information as has been obtained in connection with the details of the subject. Some of the data they contain have not been published heretofore; they have been obtained in an effort to arrive at the truth on lines in which there seemed to be little precedent. Appendix F shows the practice which has been followed in the past six or seven years on work with which the writer has been connected.

The matter thus shown is, briefly, as follows:

Appendix A—Tests of Asphalts;
" B—Examination of Felts and Fabrics;
" C—Examination of Rock Asphalts;
" D—Data as to Use of Asphalts in the United States in 1912;
" E—Abstracts from Paper, by Mr. J. W. Howard, on Asphalts;
" F—Various Plans Used in Actual Practice.

Some explanation is first due as to the reasons for introducing certain features. The water-proofing of solid-floor railroad bridges is undertaken for two reasons:

First.—To protect the metal of the floor from corrosion due to the alternately wet and dry condition of a ballasted floor;

Second.—To prevent the water, which is absorbed by the ballast and given off slowly, from dripping on a street beneath.

A reasonable depth of girders and floor makes a stiff structure, and aids in making it water-tight.

There can be but little doubt that, in all designs, the primary object should be to provide such details as will remove the water from the bridge in the quickest possible time and by the shortest route; and

further, in case of the possibility of the water being held on the bridge for any considerable time after a storm, to design the height of the water-proofing so that it will be above the highest water level. There are many places where the ballast will become very dirty in time, and at such localities this detail is important.

It is also considered inadvisable to throw all the water off the bridge at its ends, over the back walls. It is very difficult to design at this point a satisfactory detail which will prevent water from forcing its way back over the back wall and down the face of the abutment, even though the drainage back of the abutment is specially good. It is much better to collect the water on the deck of the bridge, take it below the floor by inlets and down-spouts, and discharge it below the floor on the ground, or into a sewer (if in a city). Such inlets can be made so as to be accessible from below for cleaning, and, with ordinary care, can be made satisfactory as far as leakage around them is concerned. To carry the water away quickly, there should be a number of these inlets on any bridge of considerable extent.

In the case of deck structures, the water-proofing details are simple, the principal questions to be settled being the type of water-proofing to be used and the durability of the materials. The application of the water-proofing—whatever kind may be selected—is not difficult.

In a half-through structure the conditions for water-proofing are at their worst. If the top of rail is near the top of girder, it is generally advisable to carry the water-proofing over the girder and encase its entire top in concrete. The writer wishes that a number of such girders, in which he has assisted in the design and construction, had been treated in this manner.

The finish of the water-proofing against the web of a half-through girder, the top of which is 3 ft. or more above the top of rail, is one of the most difficult problems to be solved. In some cases, it is the practice to carry the water-proofing nearly if not all the way up to the top of the girder, and protect it with a considerable thickness of concrete, but, generally, it is finished up against the web not far above the level of the top of rail. This finish, if done satisfactorily, will make a good piece of work of the structure as a whole, provided the detail in respect to water running over the back walls is guarded against. It is believed that riveting a flashing angle to the web does not provide a satisfactory detail, as it is impossible to make it continuous on account

of stiffeners and gussets. Placing a pocket of ductile, adhesive mastic (which will not harden in cold weather) as a joint between the water-proofing layer and the web is believed to give the best results, and in case of the deterioration of this asphalt, the detail is in a place where repairs can be made without interfering with traffic. The question of interference with traffic in making water-proofing repairs is one that is giving many railroad bridge engineers serious concern, and is leading slowly, but surely, to much more elaborate, effective, and expensive systems, in order that repairs may be postponed as long as possible. It is possible to make the proper kind of pure asphalt, unmixed with foreign matter, adhere to a clean surface of metal or concrete, and thus secure a tight joint. It has been found advisable to protect this pocket of asphalt with a layer of concrete to prevent the ballast, which may be carelessly thrown against the girder, from cutting into it. (See Figs. 8 and 9, Appendix F.)

As to materials to be used for the solid bridge floor, it is believed that, after the question of durability is disposed of—as one of the most important items—the most durable material, which can be shown to possess adhesion and ductility at low temperatures, and at the same time be sufficiently hard to prevent running at maximum exposure temperatures, is the most desirable—say, temperatures generally between 0° and 200° Fahr. Higher melting points are undesirable, for a number of reasons, and should not be used. The most critical time to test a bridge floor is during melting snow, and cracks which may develop at that time are sure to be channels for water.

Whether felt, fabric, or asphalt mastic shall be used, is a debatable question, and will depend somewhat on conditions. If hard pressed for head room in depth of floor construction, the use of asphalt mastic is indicated, and, though it is generally considered an undesirable material, it is believed that, with proper natural rock, proper flux, and careful mixing and placing, first-class results can be obtained, if the pure asphalt seal is used against the metal. A large bridge, of about 43 000 sq. ft., lately built, is water-tight, and recently the writer has seen materials of this character in splendid condition after 20 years' service.

Felts or fabrics, of course, contain organic matter, and, if not entirely covered with asphalt, are subject to disintegration by "rotting". It would seem, however, that if properly prepared and laid, these

materials should form a very satisfactory membrane—more satisfactory, as far as elasticity is concerned, than the mastic. A felt of inorganic material—asbestos—has all the proper qualities, from the standpoint of durability. It is generally laid in combination with a layer of treated burlap to give it additional strength. Practice sometimes protects asbestos felt with asphalt mastic instead of brick or reinforced concrete. This is probably allowable with asbestos felt, but should never be used with any of the other felts. Experience shows that hot mastic, placed on a layer of felt, or fabric treated with asphalt, will draw the asphalt out of the felt and incorporate it as part of the mastic.

The writer wishes to acknowledge the kind permission of Theodore Voorhees, M. Am. Soc. C. E., Vice-President, and W. Hunter, M. Am. Soc. C. E., Chief Engineer, Philadelphia and Reading Railway Company, and George S. Webster, M. Am. Soc. C. E., Chief Engineer, Bureau of Surveys, City of Philadelphia, to present the data in this paper, and to Mr. Edwin Chamberlain, Assistant Engineer, Philadelphia and Reading Railway Company, and R. J. Lawrence, Assoc. M. Am. Soc. C. E., for assistance in its preparation.

GENERAL SPECIFICATIONS FOR WATER-PROOFING SOLID-FLOOR RAILROAD BRIDGES.

PART I. DETAILS OF CONSTRUCTION.

1.—Depth.—The depth of steel or concrete construction shall be such as to allow a sufficient distance from top of rail to top of steel or concrete floor for proper water-proofing, and protection from the cutting action of the ballast. Under ordinary conditions, a depth of from 3.5 to 4.0 ft. from top of rail to clearance line below is sufficient.

2.—Drainage Grade.—Provision shall be made for grades of at least 1% on the floor of the bridge to remove water promptly. Where this cannot be done in the steelwork, cement concrete, with a minimum thickness of 2½ in., shall be placed so as to drain the water to the inlets.

3.—Inlets.—Cast-iron inlets shall be set at proper places in the floor and provided with movable top grates. The down-spout from each inlet shall be provided with a trap and clean-out, which shall be accessible from below the bridge. The down-spout shall be of wrought iron, and connected to a sewer or arranged according to local conditions.

4.—Details of Steelwork.—Where two longitudinal girders meet over a column, the end stiffeners shall be placed with the outstanding leg toward the center of the girder, and the girders shall be connected with ⅜-in. plates on each side of the web. A plate shall also be placed covering the joint on the top flange.

5.—Stiffening angles on the outstanding edges of gusset-plates in half-through or through girders shall be terminated below the level of the water-proofing, the gusset-plates shall be heavier, and shall be placed from 10 to 12 ft. apart.

6.—Where the top of girder approximates the same height as top of rail, the water-proofing and protection shall cover the entire top of the girder.

7.—The apron-plate from the steel floor over the back wall shall be provided with a curb angle against which to finish the water-proofing, and to this angle shall be riveted a vertical plate to prevent dirt from collecting under the apron-plate. The apron-plate shall be anchored to the back wall.

8.—Water-proofing.—General Design.—On top of the prepared surface of the concrete shall be placed either of the following:

1st.—One or more thicknesses of felt or fabric, of quality and applied as specified hereafter, together with proper protection;

2d.—Asphalt mastic at least 1½ in. in thickness, of quality and applied as specified hereafter.

9.—Felt, Burlap, or Fabric.—When water-proofing of this kind is to be used, either of the following types shall be adopted:

1st.—From four to six layers of felt;
2d.—One middle layer of treated burlap, with four layers of felt;
3d.—One layer of felt, two layers of burlap, and two layers of felt;
4th.—One middle layer of treated burlap, and two layers of asbestos felt;
5th.—Either one or two layers of treated cotton-drill fabric.

10.—Protection of Water-proofing.—After the completion of the felt or fabric water-proofing, the entire surface shall be covered and protected by one of the following methods:

1st.—Straight, hard-burned brick laid flat, with joints filled either with water-proofing compound or cement grout. Water-proofing compound should only be used as a filler on flat or nearly flat surfaces;
2d.—A layer of cement concrete from 2 to 2½ in. thick, with wire reinforcement;
3d.—A layer of about 1½ in. of asphalt mastic used only on top of asbestos felt. It is believed that no protection is necessary for the asphalt mastic.

11.—Special Drainage over Protection.—On top of the protection coat, and outside the line of the ties, a line of half-round cast-iron pipe, 6 in. in diameter, and perforated frequently, shall be placed to collect the water and convey it to the inlets.

Part II. Preparation for Water-Proofing.

12.—Preparation of the Steel.—All openings in the steelwork shall be thoroughly closed, either by caulking with burlap dipped in hot asphalt, or by the use of sheet metal sufficient to maintain the concrete base before applying the burlap and asphalt.

13.—Preparation for Water-proofing Materials.—Wherever called for by the plans, the decks of the bridges shall be protected with 1:3:5 concrete, with ¾-in. stone or gravel, mixed as specified hereafter, finished with a 1:2 mix of cement mortar, ½ in. thick, troweled to a smooth surface on top, as shown. This concrete shall be allowed to dry thoroughly so as to prevent the formation of steam when the hot water-proofing materials are applied.

14.—All vertical or sloping surfaces of concrete or steel shall be thoroughly cleaned of dust, dirt, loose particles, paint, and grease. The use of a hand-bellows is recommended for cleaning loose dust and dirt from the surfaces. For cleaning paint and grease from the steel and freshening the surfaces of asphalt, where a junction of old and new is to be made, or where a pocket of pure asphalt is used against

the girders and the felt or mastic, gasoline shall be used, either by swabbing the surface with it, or by pouring a small quantity over the surface to be cleaned and setting fire to it. The use of a blow-lamp is also recommended.

15.—These surfaces shall then be painted with two coats of approved asphalt, diluted with gasoline. The materials of the first coat shall be proportioned so as to give a brownish tint. The second coat shall have a larger quantity of asphalt.

16.—Both coats of paint shall be thoroughly applied and worked into the surfaces, so as to give a uniform coating of the asphalt.

17.—Paint shall not be applied to damp concrete or steel. The painting shall be done immediately in advance of the application of the water-proofing materials and before dust has had time to collect.

18.—If the concrete is damp before the water-proofing is applied, the surface shall be first covered with a 2-in. layer of hot sand and allowed to stand for from 1 to 2 hours, after which the sand shall be swept back, uncovering sufficient surface to begin work, and the operation repeated over a new surface.

19.—Concrete Proportions.—The cement concrete shall be proportioned by measurement of volumes. The volume of a barrel of cement, 376 lb., shall be assumed to be 3.6 cu. ft. The sand and stone shall not be packed more closely than by throwing, in the usual way, into a barrel or box at the time of measurement.

20.—Cement.—Portland cement shall be used, of the quality specified by the American Society for Testing Materials.

21.—Stone.—The stone shall be clean, hard, crushed stone, or pebbles, to be approved by the Chief Engineer, and shall be composed of the whole run of the crusher, from ¼ in. to ¾ in. in size, screened of dust and particles less than ¼ in. in greatest dimension.

22.—Sand.—The sand shall be clean and sharp, and shall be composed of grains graded from "fine to coarse," screened to reject all particles of a greater diameter than ¼ in. It shall be free from foreign matter, and subject to the approval of the Chief Engineer.

23.—Care of Sand and Stone.—Sand and stone, when delivered on the work, shall be dumped on platforms and not on the ground.

24.—Hand Mixing.—When mixed by hand, the cement and sand shall be first mixed dry and made into a mortar. The stone shall be spread on a suitable floor to a depth of about 6 in., thoroughly wetted, and the mortar evenly spread over it, care being taken that the stone of each batch is mixed as to size. The whole mass shall then be turned over four times and raked, to secure complete and uniform mixture. If the Contractor desires to use some other method, he shall submit it for approval. Should the mixture be permitted to set before placing or tamping, it shall be removed and not used. Hand-mixed batches shall not be larger than 1 cu. yd. in volume.

25.—Depositing.—All concrete shall be deposited as the Chief Engineer shall direct. It shall be of such consistency that when dumped in place it shall not require much tamping, and shall be laid with a view to be an aid to the water-tightness of the structure, and not merely a support for the water-proofing materials. All showing surfaces shall be troweled to a smooth, hard surface.

26.—In cases where concrete haunching against girders is called for by the plans, forms shall be used, and the concrete shall be of a wet consistency.

Part III. Materials and Application.

Water-Proofing Felt or Fabric and Asphalt.

27.—Materials.—On the prepared surface, apply the specified number of layers of approved saturated and coated felt, with a finished surface, and weighing about 14 lb. per 100 sq. ft.

28.—The bids shall be based on the use of the type of felt specified in Paragraph 27, but additional alternate bids will be considered, based on felts or fabrics other than these, which may be approved by the Chief Engineer. In the event of such alternate bids being made, the bidders shall present with them sufficient data as to the methods of manufacture, quality of materials, and references to places where such felts or fabrics have been used, giving dates of application.

29.—All materials shall be delivered on the work in their original packages, and properly branded.

30.—The acceptance or rejection of an asphalt shall rest with the Chief Engineer, and shall be based on the requirements stated in Paragraphs 31 to 37.

31.—The asphalt used shall consist of fluxed natural asphalt, or asphalt prepared by the careful distillation of asphaltic petroleum.

32.—It shall contain, in its refined state, not less than 98% of bitumen soluble in cold carbon-disulphide. The remaining ingredients shall be such as not to exert an injurious effect on the work.

33.—When 20 grammes are heated for 5 hours at a temperature of 325° Fahr., in a tin box 2½ in. in diameter, it shall not lose more than 2% by weight, nor shall the penetration at 77° Fahr., after such heating, be less than one-half of the original penetration.

34.—The melting point shall be between 150° and 190° Fahr.

35.—A briquette of the solid bitumen, having a cross-section of 1 sq. cm. shall show ductility at 40° Fahr., and at a temperature of 77° Fahr. shall show ductility of not less than 20 cm., the material being elongated at the rate of 5 cm. per min. (Dow moulds).

36.—All tests shall be conducted according to methods approved by the Chief Engineer.

37.—The penetration indicated herein refers to the depth of penetration in hundredths of a centimeter of a No. 2 cambric needle, weighted to 100 grammes, at 77° Fahr., acting for 5 sec.

38.—*Application.*—All flashing and reinforcing around inlets and other places specified shall be carefully executed.

39.—Water-proofing shall not be done in wet weather, or at a temperature below 32° Fahr., without special orders from the Chief Engineer. The felt shall be laid shingle fashion, the first two layers longitudinally and the last three transversely to the center line of the bridge, where five layers are called for, and as specified in detail in other cases, and shall be carried up the haunching and made secure against the girder in a satisfactory manner, or as shown on the plans. The flashing against vertical or inclined surfaces shall be in accordance with the directions of the Chief Engineer, if not indicated. The first layer of felt shall not be cemented to the floor of a steel bridge, except around the drain outlets. On an arch bridge, the first layer shall be cemented to the top of the arch. At no point shall there be less than the specified number of thicknesses.

40.—As the hot asphalt is spread, the felt shall be immediately rolled into it, and rubbed and pressed over its surface, so as to eliminate air bubbles and insure thorough sticking. One mopful of the asphalt shall not be spread over more than 1 sq. yd. of surface at one mopping. Not less than 2.5 to 3 gal. of asphalt shall be used on 100 sq. ft. of a single layer of felt. The top layer shall also be mopped and the work done so that the layers shall be one compact mass.

41.—The finish of the water-proofing against the girders or concrete shall be made with a pocket of pure elastic asphalt of the quality specified in Paragraphs 31 to 37, except that the melting point shall be between 140° and 180° Fahr., the ductility at 40° Fahr. shall be at least 3 cm., and the adhesive qualities shall be satisfactory to the Chief Engineer. The surfaces with which this material comes in contact shall be dry, absolutely free from dust or grease, and, previous to its application, shall be covered with a thin paint made by dissolving the asphalt in gasoline, as specified in detail in Paragraph 15.

42.—Particular care shall be taken to make a tight joint around gussets, stiffeners, and the ends of girders.

43.—Care shall be taken to prevent injury in any way to the water-proofing by the passing of men or wheel-barrows over it, or by throwing any foreign materials on it.

44.—After the water-proofing course has been completed, the horizontal surfaces shall be protected, as shown on the plans, by a course of straight, hard-burned and dense brick, laid flat in a bed of 1 to 3 cement mortar, with full joints. There shall be not less than ½ in. of mortar between the felt and the bricks. The brick shall not increase in weight more than 10% when immersed in water for 7 hours.

45.—The haunching, and about 18 in. in width of the horizontal surface adjacent to the haunching, shall be protected, as shown on the plans, by about 2½ in. of 1:3:5 concrete, reinforced with No. 8 and No. 10 wire cloth, electrically welded, having a 3 by 8-in. mesh.

46.—Every care shall be taken to insure satisfactory and thoroughly water-tight joints between the main layer of water-proofing and the girders; and special attention shall be given to stiffeners, gussets, etc. The water-proofing shall also be carried down over the back walls to below the elevation of the bridge seat, as shown on the plans, or as directed.

47.—Rolls of felt shall be stored on end, and not laid on their sides.

48.—Water-proofing shall be done only by experienced and expert felt water-proofers.

Natural Rock Asphalt Mastic.

49.—Rock Asphalt Mastic.—Wherever called for by the plans, the decks of bridges shall be water-proofed with natural rock asphalt mastic, as specified in Paragraph 50.

50.—The cement concrete, prepared as specified heretofore, shall be water-proofed with asphalt mastic equal in quality for the intended purpose, as to ingredients used and resistance to water, to the following specifications, and be approved as such:

Sicilian rock asphalt mastic	60 parts.
Clean, sharp, graded grit and sand to pass a sieve of 8 meshes per inch	30 parts.
Asphalt as specified in Paragraphs 30 to 37	10 parts.

These proportions shall be varied when required by special conditions on the work.

51.—The mixture shall be made at the site of the work, shall be heated to a temperature of from 250 to 300° Fahr., and shall be stirred until all the ingredients are thoroughly incorporated. It shall then be spread and thoroughly worked, to free it from voids, and shall be ironed to a smooth surface with smoothing irons, if so directed. All mastic shall be applied in two coats, making the total thickness shown on the plans. The two coats shall break joints, and the mastic shall be distributed evenly. Where the thickness of the concrete plus mastic is less than 2¼ in., the full thickness shall be made up of asphalt mastic.

52.—All mastic delivered on the work shall be properly branded. Water-proofing shall not be done in wet weather, or at a temperature below 32° Fahr., without special orders from the Chief Engineer.

53.—Pockets of asphalt shall be placed against all metal, and mastic along girders, around stiffeners, gussets, etc., as specified in detail in Paragraphs 14 to 18, inclusive, and 41.

54.—Great care shall be taken around expansion joints, drain-pipes, and similar places, where a separation may take place.

55.—After the mastic is laid, it shall be mopped with pure melted asphalt, and the surface shall be spread with a layer of clean, coarse sand, to harden the top.

56.—The pockets of asphalt placed against the girders, stiffeners, and gussets shall be protected, as shown on the plans, by about 2½ in. of 1:3:5 concrete, reinforced with No. 8 and No. 10 wire cloth, electrically welded, having a 3 by 8-in. mesh.

General Conditions.

57.—General Conditions.—The furnishing and erection of the steelwork for the bridge to be water-proofed will be executed under a separate contract, and the riveting will be completed, the erection finished, and the steel floor cleaned up, ready for the water-proofing, before the work on this contract is begun. In addition to the foregoing, the Contractor shall make a final cleaning of the steelwork before the work of water-proofing is begun.

APPENDIX A.

TESTS OF ASPHALTS. (SEE TABLE 1.)

The following notes are to be considered in connection with the interpretation of the tests recorded in Table 1.

Bitumen Soluble in CS_2.—This represents the total bitumen soluble in CS_2, and is determined by the method recommended by the American Society for Testing Materials. Generally, it may be said that 99.5% of the petroleum asphalts are soluble in CS_2. Others vary, especially the natural asphalts, some of which may run as low as about 55%, although gilsonite will dissolve to the extent of more than 99 per cent.

Bitumen Soluble in 88° P.E.—Hubbard* says:

"The term asphaltenes is commonly applied to bitumen insoluble in petroleum naptha [or ether] and malthenes to that portion which is soluble. It is of course evident that both of these terms cover a multitude of compounds, but in general it may be said that the asphaltenes tend to give body and consistency as well as adhesive properties to the products in which they are found, so that this determination serves as an indication of the mechanical stability of the material as well as its binding qualities."

The figures given are the percentages of the total bitumen thus soluble in 88° P.E.

Ductility.—This test is made by filling with asphalt a mould which has a cross-section of 1 sq. cm., soaking it in water at the desired temperature for 20 min., and then pulling it apart at the rate of 20 cm. per min. The elongation at the moment of rupture is called the ductility, and is expressed in centimeters.†

The ductility at different temperatures indicates the ability of the material to remain firm and elastic under extremes of weather. The less the range of ductility at several temperatures, the better the material for most purposes.

Penetration.—Penetration tests are made by measuring the penetration of a No. 2 standardized weighted needle at different temperatures, and under definite weights and times.

In such tests, the following weights and times are used:

At	40°	Fahr.		200	grammes	acting for	60 sec.
"	77°	"		100	"	" "	5 "
‡"	77°	"	(after heating)	100	"	" "	5 "
"	110°	"		50	"	" "	5 "

The penetration is expressed in hundredths of a centimeter.

* "Dust Preventives and Road Binders," p. 361.

† The details of the method are given in *Proceedings*, Am. Soc. for Testing Materials, 1909, Vol. IX, p. 594.

‡ This test is made after heating for 5 hours to a temperature of 325° Fahr.

Loss on Heating.—This is a volatilization test, and is made by heating a sample in the air oven for 5 hours at a temperature of 325° Fahr., and then expressing the loss as a percentage. It is believed, by investigation of the subject, that the loss of weight thus ascertained is a fair comparative indication of the loss by volatilization suffered in the course of time on exposure. It is made in a similar manner to that described by Richardson.*

Melting Point.—This is determined by preparing ½-in. cubes of the material, and measuring the temperature.†

The melting point of an asphalt is very closely related to its hardness or brittleness, but varies considerably. The determination of the proper melting point depends, almost entirely, on the conditions under which the material is to be used and how it is to be mixed and applied. High melting point materials cannot be used to apply in thin layers to cold materials, on account of the rapidity with which they cool, but can be used in mastic mixtures, if the other ingredients are hot. It is generally true that materials with a high melting point will be deficient in ductility at low temperatures.

In the tables of tests, the numbers 1, 2, etc., represent different brands of prepared asphalt; the letters "a", "b", etc., refer to different samples.

* "The Modern Asphalt Pavement."

† By the method described in *Proceedings*, Am. Soc. for Testing Materials, 1909, Vol. IX, p. 594.

APPENDIX B.

FELTS AND FABRICS. (SEE TABLE 2.)

For use in solid bridge floor water-proofing, there are a large number of felts, burlaps, and fabrics, which are treated in the shops with various asphaltic compounds, and are used to make up a compound membrane in the field by fastening the several layers together with some asphalt compound applied hot.

The tests in Table 2 are representative of such materials, as prepared by nine different manufacturers. They are intended to show the percentages of bitumen and felt or fabric per square foot, as well as the total bitumen, and its solubility in 88° P.E.

TABLE 2.—TESTS OF WATER-PROOFING FELTS AND FABRICS.

No.	Description.	Percentage of Bitumen.		Original weight, in ounces per square foot.	Bitumen, per Square Foot.		Felt, Etc., per Square Foot.		Tensile strength, in pounds per square foot.

10-*b*	" felt.....	58.25	73.80	2.40	1.40	58.33	1.00	41.66	28

The felts are generally composed of wood or vegetable fiber, with a little wool in some cases, and in one case, asbestos fiber.

As to finish, there seem to be generally two kinds of these felts: 1st, the felt simply saturated with the asphalt compound, with what might be called a rough finish; 2d, a saturated and coated felt with the finish smooth and hard. Of these, the first is much the cheaper.

Table 2 shows that though there are considerable differences in the quantity of bitumen per square foot, expressed in the form of a percentage, the actual differences are not very great.

The fabrics alluded to are of two kinds: 1st, burlap; 2d, some kind of closely-woven cotton material. These are saturated with the asphalt compound during manufacture. Burlap should never be used in an untreated state on the work, as the raw material is not easily embedded in the hot asphalt in the field, and, further, it takes up water readily from the air. The temperature of the asphalts used should not be greater than 400°, as higher temperatures are likely to burn the burlap.

The figures, 1, 2, etc., in Table 2, represent different manufactures, and the letters, *a*, *b*, etc., refer to different samples.

APPENDIX C.

Rock Asphalts. (See Table 3.)

The only rock asphalts here treated are the imported materials from Switzerland, Germany, and Sicily. The rock, as imported from these localities, contains in itself the following quantities of bitumen.*

Ragusa, Sicily.	Seyssel. France.	Verwohle.	Sicula. Sicily.	Neuchâtel. Switzerland.	Mons.
9.9%	5.9%	7.5%	10.2%	9.1%	8.9%

This rock is ground and fluxed with additional asphalt, so that, when poured into cakes and shipped to the site of the work, the percentages of bitumen vary from 13 to 18%, and it is this material which is again melted, with the addition of about 10% of flux, and incorporated with grit or small pebbles to make the mastic.

The figures in Table 3 give the results of a number of analyses of two brands of asphalt mastic. In a few cases, the granularimetric analysis of the natural rock freed from the bitumen is given. It will be noted that this runs very high in the finest particles of the limestone, which is the natural rock impregnated in both kinds of asphalts tested.

TABLE 3.—Analysis of Rock Asphalts as Delivered on the Work.

Records, in a number of cases, of long life for these imported rock mastics, make them very desirable for water-proofing purposes under certain conditions. Cases of more than 20 years' use, with the material apparently in as good condition as it was when placed, are known.

APPENDIX D.

MINERAL RESOURCES OF THE UNITED STATES FOR 1912.
PRODUCTION OF ASPHALT BY VARIETIES.

	Short tons.	Percentages.
Bitumen rock	53 041	11.7
Refined bitumen	22 852	5.1
Maltha	474	0.1
Wurtzilite (elaterite)	8 452	1.9
Gilsonite	31 478	7.0
Oil asphalt	333 213	74.2
Total	449 510	100.0

The total imports of asphalt in 1912 were 218 328 short tons.

APPENDIX E.

Extracts, from an Article Entitled "Asphalt Paving Cements and Road Binders", by Mr. J. W. Howard.*

Mr. Howard's article, though written with reference to roads and pavements, has much of interest in connection with the subject of the use of asphalts for water-proofing purposes, and the writer calls special attention to it in order that the various features may be elaborated by those interested in the subject, and ultimately form the basis of more specific data for water-proofing specifications.

What follows has been abstracted, briefly, with the object of showing some of the properties which are considered necessary in an asphalt, and without giving the laboratory methods, which are described in each case.

1. Adhesiveness, or Cementing Strength.—This is a self-evident property needed to cement together the particles of a mastic or the various layers of felt.

2. Water-proofness, or Freedom from Injury by Water.—This is important on account of the exposure of the materials to water moisture, either directly or through capillary action. The formulation of some test which can be made readily to determine this property is of special value, as it is well known that asphalts differ in the property of resisting the action of water.

3. Immutability, or Freedom from Deterioration on Exposure to Sun and Air.—This is important on account of the bad effects which may result from the heat of the sun, the action of the air, and other elements. The asphalt must retain its life and qualities. This test is made by heating, as called for in the specification presented, and noting the percentage of loss; also in examining the penetration before and after the heating.

4. Ductility.—Ductility is the ability to yield without breaking, and is an important property in asphalt used in solid-floor bridges. It is also necessary that the material should be able to contract from cold without cracking. The data for this property are embraced in the specifications, and have been studied more or less carefully. A reasonable and consistent ductility at various temperatures is a desired property.

5. Flexibility or Pliability.—Flexibility or pliability without brittleness is needed for practically the same reasons as are given for ductility, and because the asphalt should be able to yield without cracking. Very little data are available concerning this property.

6. Cohesiveness.—This is the property needed by an asphalt in order to prevent it from pulling apart or cracking within itself,

* *Engineering Record*, September 27th, 1913.

although it may adhere firmly to the materials which it is to bind together. This property is one that has not been studied in water-proofing materials, but is deserving of further care and study.

7. Malleability.—This quality is referred to by Mr. Howard, but is not required for water-proofing materials.

8. Consistency.—This is the right kind of hardness or softness necessary under various temperature changes. It is also known technically as penetration. The tests of the various asphalts and the methods of making the tests are given in Appendix A.

9. Minimum Susceptibility to Softening or Stiffening During Extreme Weather Temperatures.—All asphalts are softened by hot and stiffened by cold weather. Thus far it has been impossible to devise asphalts which will not do this. All good ones, however, do not become too soft or fluid in hot weather, or too stiff in cold weather. This is shown by penetrations at freezing and at high temperatures. (See Appendix A.)

10. Purity or High Percentage of Bitumen.—This quality is important, for several reasons. It excludes foreign matter, which is often injurious. Useless matter is not cementitious, and reduces the quantity of work that can be done with a given quantity of pure asphalt.

11. Freedom from Injury by Heat.—Because all asphalts must be heated sufficiently to apply in the work, it is important that they should not be injured by being heated and maintained at a fluid temperature for a reasonable time. The same test as for immutability may be used.

APPENDIX F.

Plans of Different Methods of Water-Proofing.

Figs. 1 to 9 illustrate progress in water-proofing design, and should be considered and studied in the order in which they are numbered, as the sequence represents what are considered to be improvements in each case.

as filler beneath mastic. Drainage beneath floor by gutters leading to down-spouts and into street gutters beneath bridge. Asphalt beneath flash angle and against web. The nipple is a bad detail. Asphalt will break loose from web of girder and allow water to seep through along web at stiffeners and gussets when flash angle is not continuous.

The cost of such work, including concrete and all drainage, is about $0.25 per sq. ft.

Fig. 2.—Half-through plate girder, with trough floor. Troughs filled with 1:3:6 concrete and water-proofed with rock asphalt mastic. Drainage to one end of bridge, or, with light or level grades, to both ends, leading to dry stone packing placed against backs of abutments. No special precaution to make asphalt adhere to girder web—will crack and let water through. Difficult to make good detail at back wall, causing water to back up, especially after freezing weather, and run on bridge seat and down abutment.

The cost of such work, including concrete and drainage, is about $0.35 per sq. ft.

Fig. 3.—Half-through plate girder, with trough floor. Very shallow girder shown in drawing, but same principle applicable to girders of greater depth. In case of proportions shown, probably it would have been wiser to have encased and water-proofed entire top flange of girder. Before applying concrete to fill troughs, all openings between girders and ends of floor sections are carefully caulked with burlap dipped in a low-melting-point asphalt. Drainage is over back wall with specially prepared, sealed joint. Water-proofing is 1½ in. of rock asphalt mastic applied in two ¾-in. layers. A V-shaped opening left along the girder web, and around stiffeners and gussets. The sides of this opening cleaned with wire brushes, bellows, and gasoline, and then painted with asphalt dissolved in gasoline. The V then filled with low-melting-point, ductile, pure asphalt.

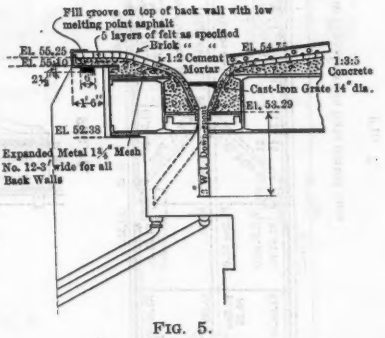

FIG. 5.

This type of floor has been very successful, and costs, complete, about $0.45 per sq. ft.

Fig. 4.—Half-through plate girders with floor-beams and with I-beam and plate floor. Bridge on a level grade. Concrete filling of 1:3:5 mix, sufficient to produce drainage grades. Water-proofing consists of five layers of surfaced felt and asphalt compound. Water-proofing carried up under top flange of girders, protected by layer of hard brick, laid flat, with joints filled with asphalt compound. Water

drains to inlets placed near ends of bridge and graded so as to prevent any water from flowing over the back walls. Drainage through grates and clean-outs into down-spouts to sewer. Half-round, perforated, cast-iron pipe placed on top of brick to assist flow of water if ballast becomes dirty. Another detail of back-wall drainage, shown in Fig. 5, has been very successful.

Costs about $0.75 per sq. ft. High on account of grade of track being level, requiring additional concrete and inlets to provide proper drainage.

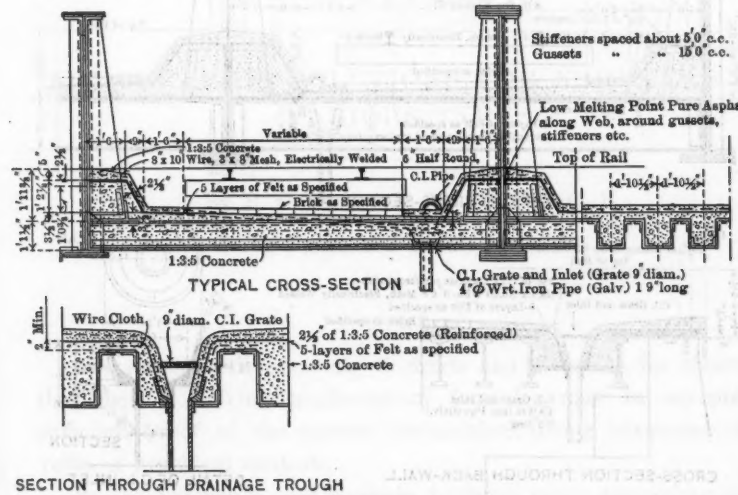

FIG. 8.

Figs. 6 and 7.—Deck viaduct with shallow-trough floor. Tracks level. Troughs filled with 1:3:5 concrete and water-proofing of same character as in Fig. 4. Drainage shown in Fig. 7. Only improvement suggested is use of cement mortar in place of asphalt for brick protection. Very successful.

Cost, $0.65 per sq. ft. High on account of level grade on viaduct, requiring additional concrete and inlets to provide proper drainage.

Figs. 8 and 9.—Half-through plate girders. Fig. 8 with trough floor and Fig. 9 with I-beams and plates. Filling with 1:3:5 concrete. Water-proofing, five layers of surfaced asphalt felt with asphalt compound, and protected with hard-burned brick in 1:3 cement mortar on flat floor and 1:3:5 concrete, reinforced with No. 8 and No. 10 wire, 3 by 8-in. mesh, electrically welded in gutters and over haunching. Pocket of low-melting-point, pure asphalt, carefully put in as

seal against girders and around stiffeners and gussets before protection is placed. Drainage to inlets. No water going over back walls. Water removed from copings by special inlets built in masonry.

Under contract and not completed at present time. Cost about $0.62 to $0.80 per sq. ft., including all drainage details.

NOMOGRAPHIC SOLUTIONS FOR FORMULAS OF VARIOUS TYPES.

By R. C. Strachan, M. Am. Soc. C. E.

To be Presented February 3d, 1915.

Synopsis.

The present extensive use of charts and diagrams for shortening the labor of solving mathematical formulas may be accepted as sufficient proof of the general recognition among engineers of the value of graphical methods.

By the commonly used methods, however, many expressions cannot be represented without the use of a large number of intersecting lines, which cause the chart to be more or less confusing and difficult to read.

This paper shows the application of the nomographic principle of representation to a number of extensively used formulas, presenting illustrative charts and detailed descriptions of their construction.

The underlying principle is that of plotting the scales representing the variables in such a way that a line crossing the scales anywhere gives a set of readings which satisfy the equation. This principle has not received from American engineers that degree of attention to which it is entitled by reason of its great value and wide range

Note.—These papers are issued before the date set for presentation and discussion. Correspondence is invited from those who cannot be present at the meeting, and may be sent by mail to the Secretary. Discussion, either oral or written, will be published in a subsequent number of *Proceedings*, and, when finally closed, the papers, with discussion in full, will be published in *Transactions*.

of applicability, and the object in presenting the paper is to call attention to this somewhat neglected labor-saving device.

A nomographic representation, or, more concisely, a nomograph of a formula, may be defined as a plot or chart on which appear scales for the variables involved in the formula, their relative magnitudes and relative positions being such that corresponding values of the variables are found on a line crossing the scales.

By the expression "corresponding values" is meant a set of values which satisfy the equation represented by the nomograph; and the crossing line, therefore, is properly termed an isopleth.

The aim is to substitute the simplest possible mechanical operation for the labor of solving the formula by computation; and, with this in view, the nomograph should preferably be designed so that its isopleths are rectilinear.

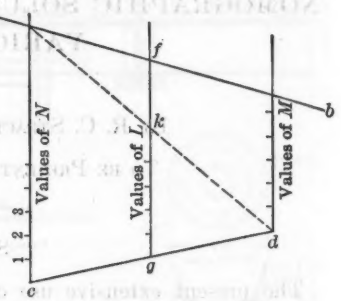

FIG. 1.

Take, as a simple illustration, three parallel scales of equal parts, starting from a common base line, $c\ d$, Fig. 1, and suppose the L line to be equidistant from the other two. Draw any straight line, $a\ b$, across the scales. Then $f\ g = f\ k + k\ g = \frac{1}{2} M + \frac{1}{2} N$.

The figure is a nomograph of the expression $L = \frac{1}{2}(M + N)$ and the line, $a\ b$, is an isopleth, its intersection showing by the scale readings a set of values which satisfy the equation.

If $g\ d = \frac{1}{3} c\ d$, $f\ g = \frac{1}{3} N + \frac{2}{3} M$, and the nomograph represents $L = \frac{N + 2\ M}{3}$, or $3\ L = N + 2\ M$, or $N = 3\ L - 2\ M$.

If the units on the L scale are made one-half as great as those on the other scales, the nomograph represents $L = \frac{2\ N + 4\ M}{3}$, or $3\ L = 2\ N + 4\ M$.

As another illustration, in Fig. 2, let $c\ d = d\ e$, and lay off the parallel scales for P and Q as shown. This is a nomograph of $P = \frac{1}{2} Q$, and any straight line drawn from c through the scales is an isopleth.

Evidently, changes in the positions and magnitudes of the scales may also be made in this diagram, with corresponding effects on the expression represented.

If in place of the numbers we lay off their logarithms, we may read products instead of sums; exponents may be affected by changing the distance between scales, and numerical coefficients may be introduced by varying longitudinally the position of one or more scales.

A straight-edge may be used to indicate the position of an isopleth, or, for greater ease in reading the scales, a strip of transparent celluloid having a line scratched on it, will be found very convenient.

The mathematical principles involved are very simple, and their application is easy when the right clue has been discovered. Many expressions which in their usual forms appear to be hopeless can be adapted to nomographic representation by a proper transformation; but the necessary change may not suggest itself until the equation has been studied somewhat thoroughly.

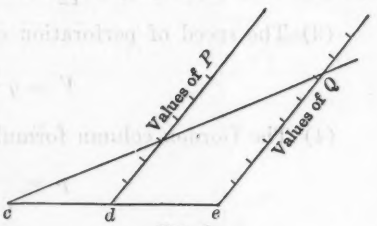

FIG. 2.

It will be found that, as a rule, scales of natural numbers are suitable for formulas in which the signs + and — appear; and logarithmic scales are adapted to those in which quantities affected by exponents must be multiplied or divided. In many cases, however, a formula in which there is an integral exponent may be transformed so as to permit the use of natural numbers for its nomographic scales.

Great ingenuity has been exhibited by various writers in constructing charts for formulas of much complexity: the work of Professor Maurice d'Ocagne is perhaps the most exhaustive, though both Soreau and Seco have shown that this field possesses astonishing possibilities.

Quite a large number of contributed articles on the subject have been published,* those of Professor John B. Peddle having been put into book form. Articles have also appeared by B. D. Dean, M. Am. Soc. C. E., and Mr. Richard Muller.†

At intervals, charts for complicated formulas have been published without explanation, except as to the method of using them; and though

* In the *American Machinist.*
† *Engineering News*, September 3d, 1908.

they are valuable to those who are satisfied as to their correctness, they are virtually empirical when used blindly.

Among earlier engineers, Messrs. Ganguillet and Kutter charted their well-known formula, and important additions to the chart were made afterward by Rudolph Hering, M. Am. Soc. C. E., who embodied his results in a paper* entitled "The Flow of Water in Small Channels."

A most interesting study of nomography was made by Mr. Rodolphe Soreau.† In addition to a new form of chart for Kutter's formula, Soreau has constructed nomographs for the solution of the following:

(1) The weir formula, in metric units,

$$Q = 95\ (H + 0.7)^{\frac{3}{2}};$$

(2) The volume of a conical frustum,

$$V = \frac{\pi\, h}{12}\ (D^2 + D\, d + d^2);$$

(3) The speed of perforation of a projectile,

$$V = q\, \frac{a^{0.75}}{p^{0.5}}\, t^{0.7};$$

(4) The Gordon column formula, expressed in metric units,

$$p = \frac{s}{1 + \dfrac{l^2}{n\, r^2}};$$

(5) The formula for the thickness of hollow cylinders,

$$m = \sqrt{\frac{R + p}{R - p}} - 1;$$

(6) The barometric formula for determining heights,

$$N = 18\,293\ (1 + 0.002837\ \text{cos. } 2\ \lambda) \left[1 + \frac{2\ (T + t)}{1\,000}\right] \text{log. } \frac{H}{h};$$

any many others.

The diagrams in common use almost invariably take the form of the locus of an equation referred to rectangular co-ordinates; and, in order to make them cover the required range, it is frequently necessary to use a great number of lines. This makes the diagram confusing and difficult to read, thus introducing chances for error. In case any of the factors are affected by exponents, the disadvantages of diagrams of this form are greatly increased.

---

* *Transactions*, Am. Soc. C. E., Vol. VIII, p. 1.

† The results are found in the Memoirs of the Society of Civil Engineers of France for 1901.

The immense superiority of the nomograph is due to the following facts: that it is easily read with precision on account of having few lines; that it saves much valuable time, providing in effect a perfect tabulation of all possible values within the limits of the chart; and that it enables one to see instantly the effect of a change, whether small or great, in any of the variables. Furthermore, the solutions are equally simple, whichever quantity in the formula is unknown.

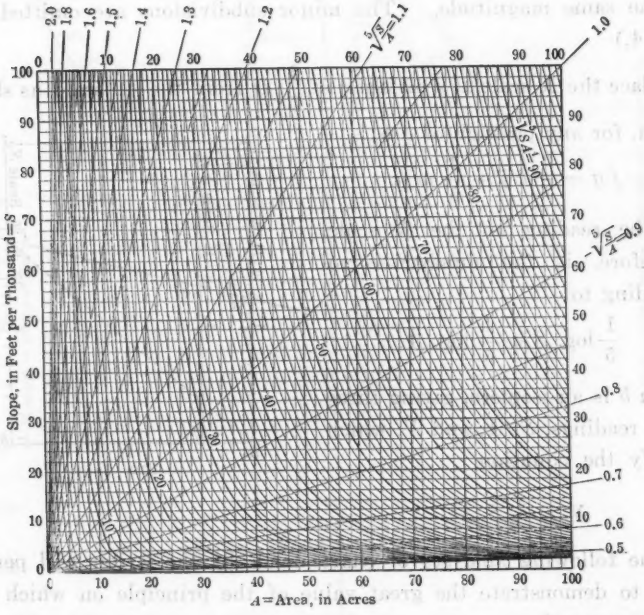

FIG. 3.

The following comparison will illustrate these points: In a recent issue of a technical periodical a correspondent gives the diagram, Fig. 3, for finding $\sqrt[5]{S\,A^4}$ in the McMath run-off formula.

He explains that, to construct this, it is necessary to compute $\sqrt[5]{\frac{S}{A}}$ and derive from this $\sqrt[5]{S\,A^4}$ for a number of cases sufficient to give all the points required for plotting the curves.

The finished diagram contains four sets of carefully plotted lines, and the intersections near the lower and left-hand edges are very indefinite.

A nomograph of this radical consists of three scales, and may be constructed with great ease and without computation, as follows:

Let $N = \sqrt[5]{S\,A^4}$.

Then $\log.\ N = \frac{1}{5}\log.\ S + \frac{4}{5}\log.\ A$.

Lay off three parallel scales of the logarithms of numbers from 1 to the limit desired (Fig. 4), making all three with logarithmic units of the same magnitude. (The minor subdivisions are omitted from Fig. 4.)

Place the N scale at a distance of $\frac{1}{5}\ D$ from the A scale as shown. Then, for any position of $a\ b$,

$$f\ g = \frac{1}{5}\,k\ l + \frac{4}{5}\,m\ n.$$

The reading on the N scale, therefore, is the number corresponding to

$$\frac{1}{5}\log.\ S + \frac{4}{5}\log.\ A,$$

and $a\ b$ is an isopleth, giving three scale readings, S, A, and N, which satisfy the equation,

$$N = \sqrt[5]{S\,A^4}.$$

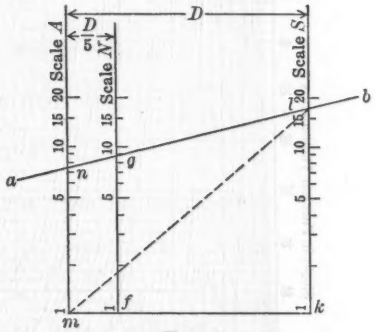

FIG. 4.

The following analyses of charts made by the writer will perhaps serve to demonstrate the great value of the principle on which they are constructed.

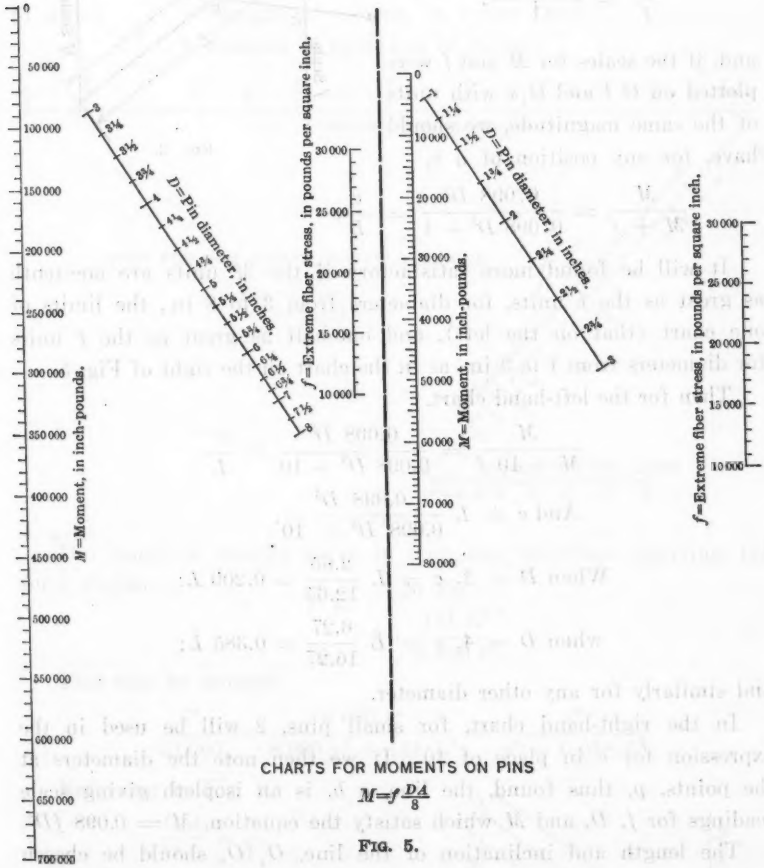
Chart for Pin Moments.—Tables for bending moments on pins are found in all engineers' pocketbooks, but interpolations are frequently necessary, particularly in reviewing a completed design. For this purpose a nomograph is especially useful, and a very neat one may be constructed with scales of natural numbers for moments and stresses. (Fig. 5.)

Let M = moment, in inch-pounds;
D = diameter of the pin, in inches;
A = area of the pin, in square inches;
f = extreme fiber stress, in pounds per square inch.

Then $M = f \frac{D A}{8}$.

Or, by substituting $0.7854\ D^2$ for A,

$$M = 0.098\ f\ D^3.$$



CHARTS FOR MOMENTS ON PINS

$M = f \frac{DA}{8}$

FIG. 5.

In Fig. 6, let the scales of equal parts for f and M be parallel, with the zeros at O and O_1, as shown, and plotted at a convenient distance apart. Connect O_1 and O, and let any line, $a\ b$, intersect the three lines.

Then $$\frac{O\,l}{O_1\,k} = \frac{c}{e},$$

therefore,

$$\frac{O\,l}{O\,l + O_1\,k} = \frac{c}{L}.$$

Also,

$$\frac{M}{f} = \frac{0.098\ D^3}{1},$$

and, if the scales for M and f were plotted on $O\ l$ and $O_1 k$ with units of the same magnitude, we should have, for any position of $a\ b$,

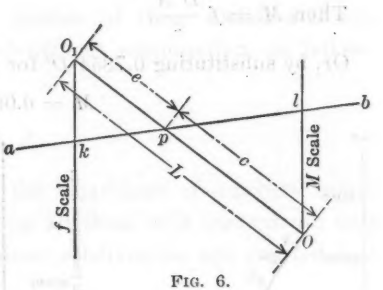


FIG. 6.

$$\frac{M}{M + f} = \frac{0.098\ D^3}{0.098\ D^3 + 1} = \frac{c}{L}.$$

It will be found more satisfactory if the M units are one-tenth as great as the f units, for diameters from 3 to 8 in., the limits of one chart (that on the left), and one-half as great as the f units for diameters from 1 to 3 in., as in the chart on the right of Fig. 5.

Then for the left-hand chart,

$$\frac{M}{M + 10\,f} = \frac{0.098\ D^3}{0.098\ D^3 + 10} = \frac{c}{L}.$$

$$\text{And } c = L\ \frac{0.098\ D^3}{0.098\ D^3 + 10}.$$

$$\text{When } D = 3,\ c = L\ \frac{2.65}{12.65} = 0.209\ L;$$

$$\text{when } D = 4,\ c = L\ \frac{6.27}{16.27} = 0.385\ L;$$

and similarly for any other diameter.

In the right-hand chart, for small pins, 2 will be used in the expression for c in place of 10. If we then note the diameters at the points, p, thus found, the line, $a\ b$, is an isopleth giving scale readings for f, D, and M which satisfy the equation, $M = 0.098\ fD^3$.

The length and inclination of the line, $O_1\ O$, should be chosen so as to give good intersections within the limits of the chart. A unit of 1 in. to 5 000 lb. for the f scale will be suitable for practical purposes.

Chart for Column Formula.—The Gordon column formula, when suitably transformed, may also be adapted to nomographic representation obtained by the relation of similar triangles.

The constants used in the chart, Fig. 7, are 20 000 and 8 000, or,

$$P = \frac{20\,000}{1 + \frac{l^2}{8\,000\,r^2}}$$

in which l = length of column, in inches; and
r = radius of gyration, in inches.

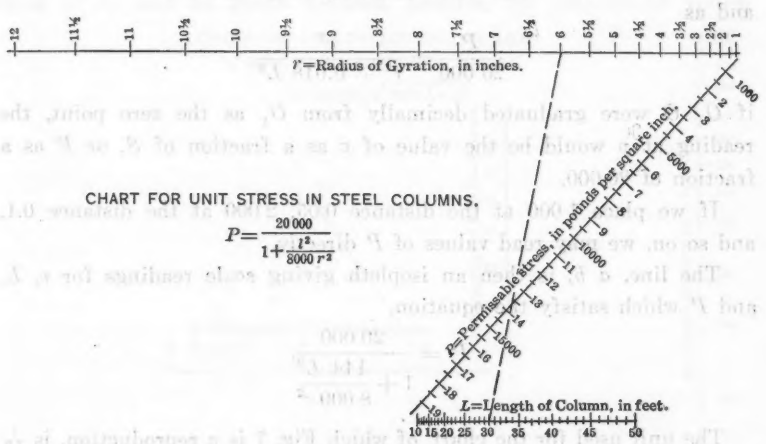

FIG. 7.

The length is usually given in feet, and therefore, inserting $12L$ for l, we have

$$P = \frac{20\,000}{1 + \frac{144\,L^2}{8\,000\,r^2}}.$$

This may be written

$$\frac{P}{20\,000} = \frac{8\,000\,r^2}{8\,000\,r^2 + 144\,L^2} = \frac{r^2}{r^2 + 0.018\,L^2}.$$

Referring to Fig. 8,

$$\frac{O_1 k}{O\,l} = \frac{c}{d}.$$

Therefore,

$$\frac{O_1 k}{O_1 k + O\,l} = \frac{c}{S}.$$

If now we lay off from O_1 1, 4, 9, 16, etc., units, placing the numbers 1, 2, 3, 4, at these points, and similarly from O 0.018 × 1,

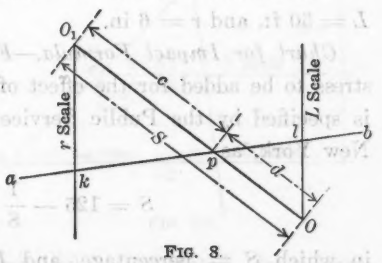

FIG. 8.

0.018×4, 0.018×9, 0.018×16 units, in other words, making the unit for the L scale 0.018 time the unit for the r scale, we shall have

$$\frac{r^2}{0.018\ L^2} = \frac{c}{d},$$

therefore,

$$\frac{r^2}{r^2 + 0.018\ L^2} = \frac{c}{S},$$

and as

$$\frac{P}{20\,000} = \frac{r^2}{r^2 + 0.018\ L^2},$$

if $O_1\ O$ were graduated decimally from O_1 as the zero point, the reading at p would be the value of c as a fraction of S, or P as a fraction of 20 000.

If we place 1 000 at the distance 0.05, 2 000 at the distance 0.1, and so on, we may read values of P directly.

The line, $a\ b$, is then an isopleth giving scale readings for r, L, and P which satisfy the equation,

$$P = \frac{20\,000}{1 + \frac{144\ L^2}{8\,000\ r^2}}.$$

The unit used for the chart, of which Fig. 7 is a reproduction, is $\frac{1}{10}$ in. for the r scale, and the distance, $O_1\ O$, is 10 in. These dimensions, of course, must be chosen with regard to the degree of precision desired in the scale readings. When constructed as stated, the value of P may be read to 100 lb.

Good intersections may always be obtained, since P is the same for $\frac{L}{r}$ and $\frac{n\ L}{n\ r}$.

The broken line on the chart shows the solution for the case $L = 30$ ft. and $r = 6$ in.

Chart for Impact Formula.—Fig. 9.—The percentage of live-load stress to be added for the effect of impact in designing bridge trusses is specified by the Public Service Commission of the First District, New York, as

$$S = 125 - \frac{1}{8}\sqrt{2\,000\ L - L^2}$$

in which S = percentage, and L = length of load producing the stress to which the percentage, S, is to be added.

If we represent $2\,000\ L - L^2$ by q, this may be written

$$125 - S = \frac{1}{8}\sqrt{q}.$$

Also, $$\log.\ (125 - S) = \frac{1}{2}\log.\ q - \log.\ 8.$$

The series of values of q, taken with suitable intervals in the value of L, may be easily deduced, because, for consecutive values

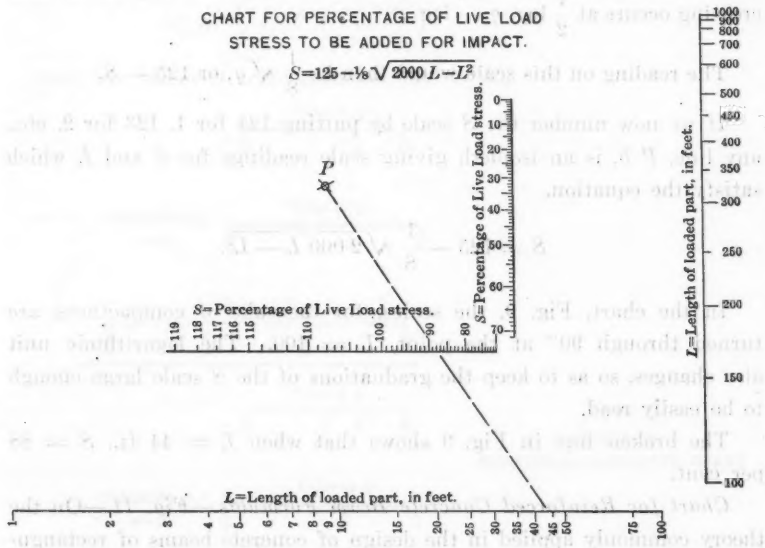

FIG. 9.

of L differing by unity, the consecutive values of q differ by $(2\,000 - 3)$, $(2\,000 - 5)$, $(2\,000 - 7)$, etc.

When $L = 1$,	$q = 1999$	$\log. q = 3.301$
2	3996	3.601
3	5991	3.777
4	7984	3.902
5	9975	3.999

Referring to Fig. 10, lay off the logarithms of q from the point, f, marking 1 opposite log. 1999, 2 opposite log. 3996, etc.

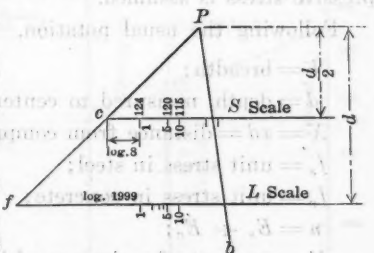

FIG. 10.

From the extremities of this scale, when completed, draw lines to a point, P, and place the line, S, parallel to the line, L, at a dis-

tance of $\frac{1}{2}d$ from it. If a logarithmic scale of the same unit magnitude as the scale, L, were placed on the line, S, beginning at c, any straight line from P through the L scale would give the number corresponding to $\frac{1}{2}$ log. q at the point of crossing the line, S; but, by beginning at a distance of 0.903 = log. 8 from c, the point of crossing occurs at $\frac{1}{2}$ log. q — log. 8.

The reading on this scale would then be $\frac{1}{8}\sqrt{q}$, or $125 - S$.

If we now number the S scale by putting 124 for 1, 123 for 2, etc., any line, $P\ b$, is an isopleth giving scale readings for S and L which satisfy the equation,

$$S = 125 - \frac{1}{8}\sqrt{2\,000\,L - L^2}.$$

In the chart, Fig. 9, the scales, for the sake of compactness, are turned through 90° at the point, $L = 100$. The logarithmic unit also changes, so as to keep the graduations of the S scale large enough to be easily read.

The broken line in Fig. 9 shows that when $L = 44$ ft., $S = 88$ per cent.

Chart for Reinforced Concrete Beam Formulas.—Fig. 11.—On the theory commonly applied in the design of concrete beams of rectangular cross-section reinforced on the tension side, the tensile strength of the concrete is neglected and a straight-line variation in compressive stress is assumed.

Following the usual notation,

b = breadth;
d = depth, measured to center of reinforcement;
$X = xd$ = distance from compression side to neutral axis;
f_s = unit stress in steel;
f_c = unit stress in concrete;
$n = E_s \div E_c$;
M = moment of resistance of beam;
p = percentage of reinforcement;
a = area of reinforcement per unit width = $p\ d$.

Then $$X = x\,d = d\left(\sqrt{2\,p\,n + p^2 n^2} - p\,n\right),$$

$$a = p\,d = \frac{d}{2\left(\frac{f_s}{f_c} + \frac{f_s^2}{n\,f_c^2}\right)},$$

$$M_s = f_s\,p\,d^2\left(1 - \frac{x}{3}\right),$$

$$M_c = \frac{1}{2}\,f_c\,d^2\left(x - \frac{x^2}{3}\right).$$

And, for balanced reinforcement, $M_s = M_c$.

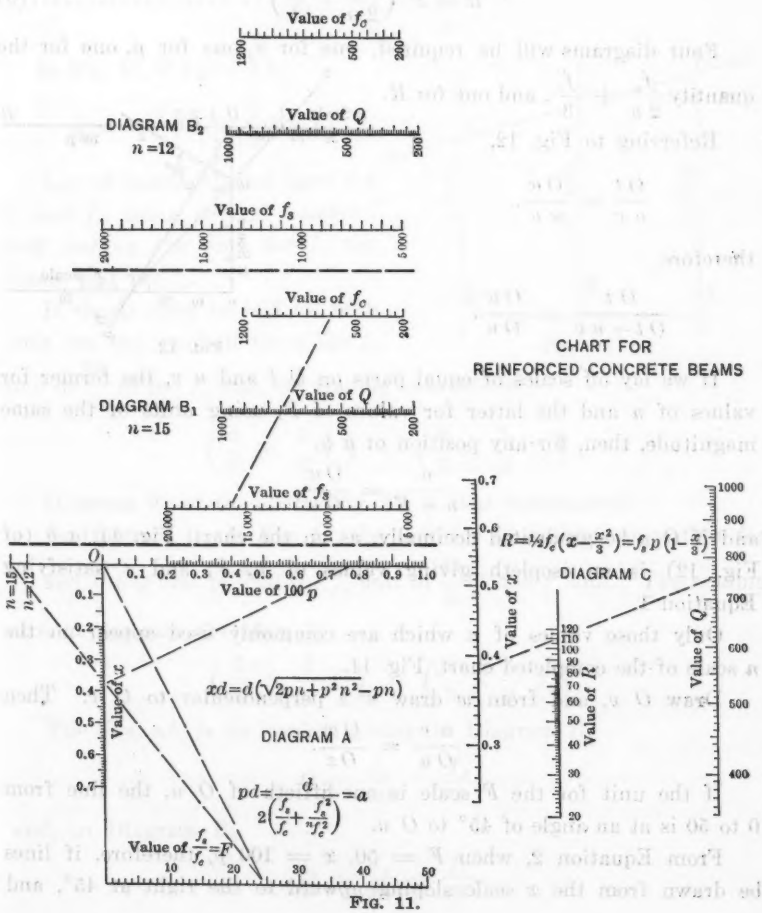

FIG. 11.

tance of $\frac{1}{2}d$ from it. If a logarithmic scale of the same unit magnitude as the scale, L, were placed on the line, S, beginning at c, any straight line from P through the L scale would give the number corresponding to $\frac{1}{2}$ log. q at the point of crossing the line, S; but, by beginning at a distance of 0.908 = log. 8 from c, the point of crossing occurs at $\frac{1}{2}$ log. q — log. 8.

The reading on this scale would then be $\frac{1}{8}\sqrt{q}$, or $125 - S$.

If we now number the S scale by putting 124 for 1, 123 for 2, etc., any line, $P\ b$, is an isopleth giving scale readings for S and L which satisfy the equation,

$$S = 125 - \frac{1}{8}\sqrt{2\,000\,L - L^2}.$$

In the chart, Fig. 9, the scales, for the sake of compactness, are turned through 90° at the point, $L = 100$. The logarithmic unit also changes, so as to keep the graduations of the S scale large enough to be easily read.

The broken line in Fig. 9 shows that when $L = 44$ ft., $S = 88$ per cent.

Chart for Reinforced Concrete Beam Formulas.—Fig. 11.—On the theory commonly applied in the design of concrete beams of rectangular cross-section reinforced on the tension side, the tensile strength of the concrete is neglected and a straight-line variation in compressive stress is assumed.

Following the usual notation,

b = breadth;
d = depth, measured to center of reinforcement;
$X = xd$ = distance from compression side to neutral axis;
f_s = unit stress in steel;
f_c = unit stress in concrete;
$n = E_s \div E_c$;
M = moment of resistance of beam;
p = percentage of reinforcement;
a = area of reinforcement per unit width = $p\,d$.

Then $$X = x\,d = d\left(\sqrt{2\,p\,n + p^2 n^2} - p\,n\right),$$

$$a = p\,d = \frac{d}{2\left(\frac{f_s}{f_c} + \frac{f_s^2}{n\,f_c^2}\right)},$$

$$M_s = f_s\,p\,d^2\left(1 - \frac{x}{3}\right),$$

$$M_c = \frac{1}{2}\,f_c\,d^2\left(x - \frac{x^2}{3}\right).$$

And, for balanced reinforcement, $M_s = M_c$.

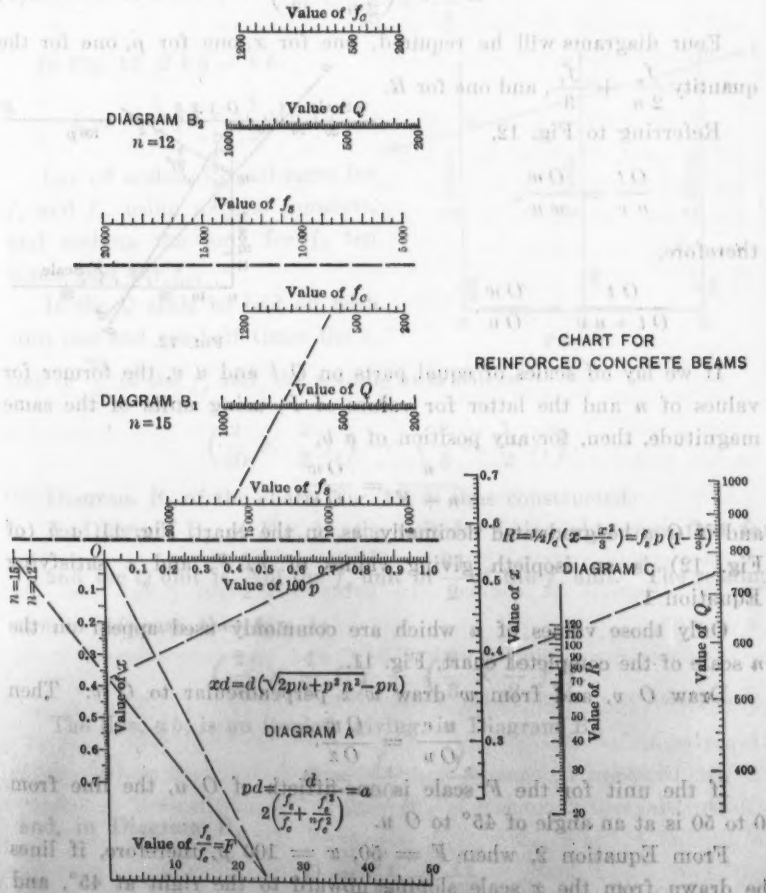

FIG. 11.

These expressions may be transformed so as to adapt them to nomographic representation.

If $$\frac{f_s}{f_c} = F,$$

and the moment of resistance $R\ b\ d^2$, or $R\ d^2$ per unit width,

Then $$x = \frac{n}{n+F} \quad \ldots\ldots(1)$$

$$p = \frac{x}{2F} \quad \ldots\ldots(2)$$

$$R = x^2\left(\frac{f_s}{2n} + \frac{f_c}{3}\right) \quad \ldots\ldots(3)$$

Four diagrams will be required, one for x, one for p, one for the quantity $\frac{f_s}{2n} + \frac{f_c}{3}$, and one for R.

Referring to Fig. 12,

$$\frac{O\,t}{u\,v} = \frac{O\,w}{w\,u},$$

therefore,

$$\frac{O\,t}{O\,t + u\,v} = \frac{O\,w}{O\,u}.$$

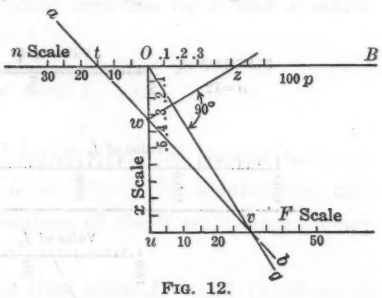

FIG. 12.

If we lay off scales of equal parts on $O\ t$ and $u\ v$, the former for values of n and the latter for values of F, using units of the same magnitude, then, for any position of $a\ b$,

$$\frac{n}{n+F} = \frac{O\,w}{O\,u},$$

and if $O\ u$ be graduated decimally, as on the chart, Fig. 11, $a\ b$ (of Fig. 12) is an isopleth giving values of n, F, and x satisfying Equation 1.

Only those values of n which are commonly used appear on the n scale of the completed chart, Fig. 11.

Draw $O\ v$, and from w draw $w\ z$ perpendicular to $O\ v$. Then

$$\frac{u\,v}{O\,u} = \frac{O\,w}{O\,z}.$$

If the unit for the F scale is one-fiftieth of $O\ u$, the line from 0 to 50 is at an angle of 45° to $O\ u$.

From Equation 2, when $F = 50$, $x = 100\ p$, therefore, if lines be drawn from the x scale sloping upward to the right at 45°, and

if the intersections with $O\ B$ are marked with the same figures as the points on the x scale from which they start, we shall have the scale of 100 p on $O\ B$.

A line, $O\ g$, through the F scale and a line perpendicular to $O\ g$ through w and $O\ B$ will then give values of F, x, and p, satisfying Equation 2. This completes Diagram A of the chart, Fig. 11.

To obtain R it is necessary first to obtain $\frac{f_s}{2\ n} + \frac{f_c}{3}$. Denoting this quantity by Q, when $n = 15$,

$$Q = \frac{f_s}{30} + \frac{f_c}{3}.$$

In Fig. 13, if $k\ g = k\ h$,

$$k\ m = \frac{1}{2}\ g\ n + \frac{1}{2}\ h\ p.$$

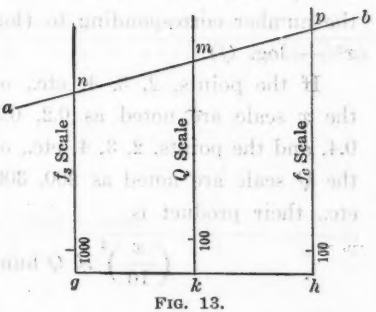

FIG. 13.

Lay off scales of equal parts for f_s and f_c, using natural numbers, and making the unit for f_c ten times that for f_s.

If the Q scale be laid off with unit one and one-half times the f_c unit or $\frac{30}{2}$ of the f_s unit, the reading at m will be

$$\left(\frac{2}{30} \times \frac{1}{2}\ f_s\right) + \left(\frac{2}{3} \times \frac{1}{2}\ f_c\right).$$

Diagram B_1 of the chart, Fig. 11, is thus constructed.

In Diagram B_2, of Fig. 11, the unit for f_c is eight times that for f_s, and the Q unit is $\frac{3}{2}$ of the f_c unit or $\frac{24}{2}$ of the f_s unit. The reading at m in this case, therefore, is

$$\left(\frac{2}{24} \times \frac{1}{2}\ f_s\right) + \left(\frac{2}{3} \times \frac{1}{2}\ f_c\right).$$

The line, $a\ b$, is an isopleth giving, in Diagram B_1,

$$Q = \frac{f_s}{30} + \frac{f_c}{3},$$

and, in Diagram B_2,

$$Q = \frac{f_s}{24} + \frac{f_c}{3}.$$

Diagram C, of Fig. 11, is constructed to give the product $x^2Q = R$, as follows:

Place the R line as shown in Fig. 14, making $k\,g = \frac{1}{3}\,g\,h$. Lay off the logarithms of x and Q on their respective lines, using the same unit. Then, for any position of $a\,b$,

$$k\,m = \frac{2}{3}\log.\ x + \frac{1}{3}\log.\ Q = \frac{1}{3}(\log.\ x^2 + \log.\ Q).$$

The R scale is laid off with unit one-third of that used for x and Q, making the reading at m the number corresponding to (log. x^2 + log. Q).

If the points, 2, 3, 4, etc., on the x scale are noted as 0.2, 0.3, 0.4, and the points, 2, 3, 4, etc., on the Q scale are noted as 200, 300, etc., their product is

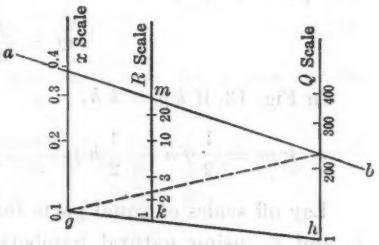

FIG. 14.

$$\left(\frac{x}{10}\right)^2 \times Q \text{ hundreds} = x^2\,Q \text{ units}.$$

Diagram C is then a nomograph for the expression, $R = x^2Q$, Q being taken from Diagram B_1 when $n = 15$, and from Diagram B_2 when $n = 12$, f_c and f_s being in pounds per square inch, b and d in inches, and $R\,b\,d^2$ in inch-pounds.

To illustrate the use of the chart, Fig. 11, assume $f_s = 16\,000$, $f_c = 650$, $n = 15$, and $b = 12$ in.

Moment of external forces = 517 000 in-lb.

On Diagram A connect the point $n\,15$ with $F\,24.6$ and read $x = 0.38$.

Connect the origin, O, with $F\,24.6$, and, on a perpendicular to this line, drawn from 0.38 on the x scale, read $100\,p = 0.77$, or $p = \frac{77}{100}$ of 1 per cent.

On Diagram B_1 connect f_s 16 000 with f_c 650, and read $Q = 750$.

On Diagram C connect x 0.38 with Q 750, and read $R = 109$.

Then $517\,000 = 109 \times 12\ d^2$,

therefore, $d = 20$ in.

Allowing 2 in. of concrete below the center of reinforcement, the required beam would then be 12 by 22 in., and the steel area would be 0.77% of 240 sq. in. = 1.85 sq. in.

Many hydraulic formulas contain fractional exponents, and are cumbersome on account of the time required for their solution. This difficulty is partly overcome by tabulating the results for a series of cases. Interpolations in such tables, however, are not invariably

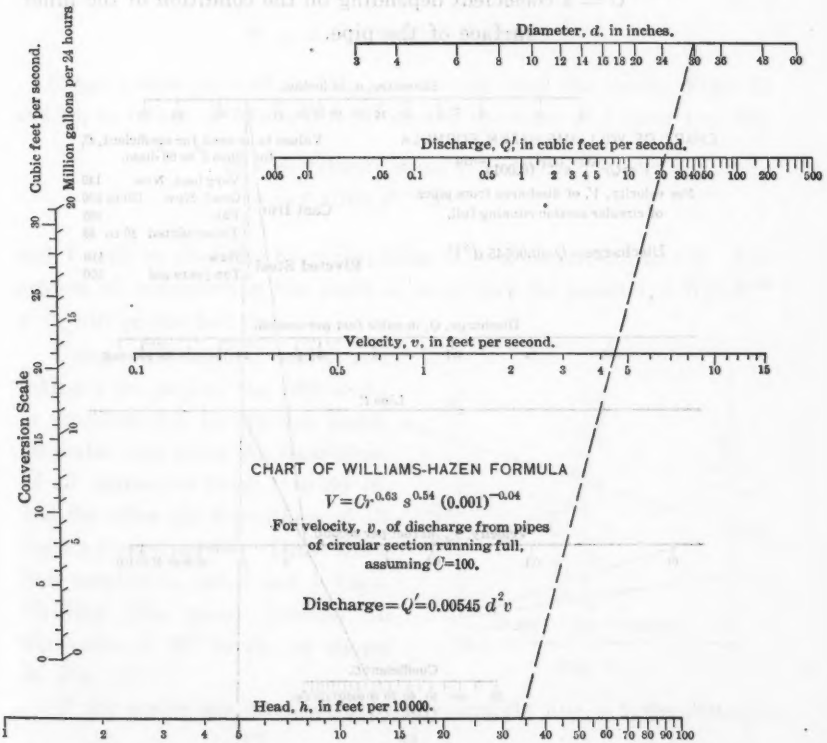

FIG. 15.

simple, and resort is had to many expedients to simplify the work. Special "hydraulic slide-rules" have been devised, which give, with sufficient precision, the results of the formula for which they are designed, but naturally such special rules can be of no general utility.

The charts for the Williams-Hazen formula, Figs. 15 and 16, are given as examples of the beauty of the nomograph in its application to the solution of an exponential equation.

Charts for Williams-Hazen Formula.—As usually stated, this formula is

$$V = Cr^{0.63}S^{0.54}0.001^{-0.04},$$

in which V = velocity, in feet per second;
r = mean hydraulic radius;
S = slope or ratio of rise to length;
C = a coefficient depending on the condition of the inner surface of the pipe.

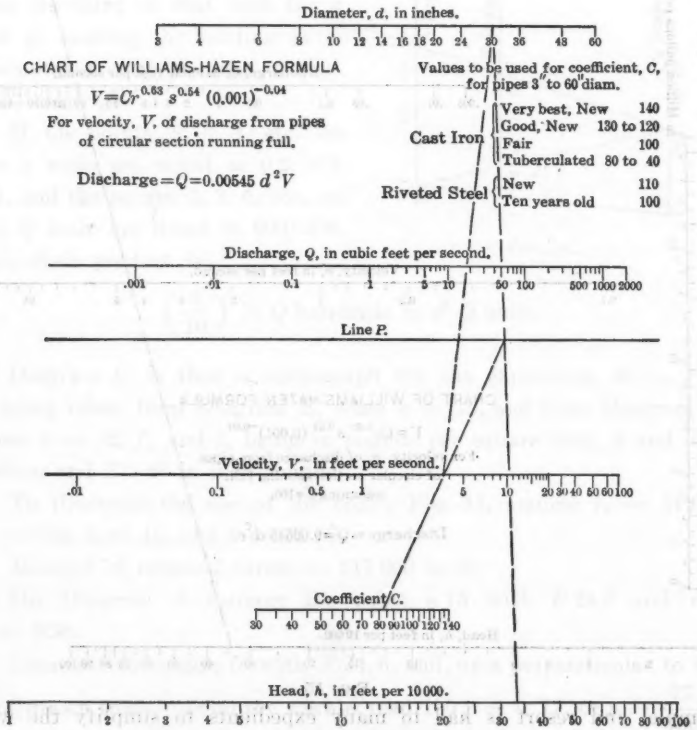

FIG. 16.

In constructing a nomograph of this formula, applicable to pipes of circular section running full, it will be convenient first to transform it so as to express r in terms of the diameter, and s as feet of head in 10 000 ft.

Letting d = diameter of pipe, in inches;
and h = feet of head in 10 000 ft.,

then $$r = \frac{D\text{ (feet)}}{4} = \frac{d\text{ (inches)}}{48},$$

and $$S = \frac{h}{10\,000}.$$

Making these substitutions, we obtain

$$V = 0.000796\ C\ d^{0.63}\ h^{0.54}.$$

C has values from 30 to 140, and we will limit the charts, Figs. 15 and 16, to values of d from 3 to 60 in. and to values of h from 1 to 100.

If v = velocity when $C = 100$,

$$v = 0.0796\ d^{0.63}\ h^{0.54},$$

and V will be obtained by multiplying v by a factor, 0.3 to 1.4. The process of constructing the chart so as to give the product, $0.0796\ d^{0.63}\ h^{0.54}$, will be the first step.

Using the decimal scale, and taking ½ in., or 1 on the 20th scale, to represent 0.1, lay off two parallel scales, one being the logarithms of all diameters from 1 to 60 in. and the other the logarithms of all the h's from 1 to 100. Draw the v line parallel to the d and h lines, dividing the space between in the ratio of 63 to 54, as shown in Fig. 17.

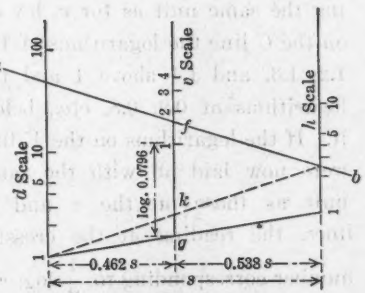

FIG. 17.

If the scales are intersected by any straight line, $a\ b$, the distance, $f\ g = f\ k + k\ g = \frac{63}{117}\log.\ d + \frac{54}{117}\log.\ h$. If the v's were laid off by the scale of 20ths beginning at the point, g, the reading at f would give the product, $d^{\frac{63}{117}}\ h^{\frac{54}{117}}$.

$\frac{63}{117} = 0.855 \times \frac{63}{100}$, hence if the logarithms of the v's are laid off with a unit of (½ in. × 0.855) to 0.1, the reading at f would give the

product, $d^{0.63}\ h^{0.54}$. This may be accomplished by using for the v's the scale of 20ths after multiplying the logarithms by 0.855, thus:

$$\text{log. } 2 = 0.301 \times 0.855 = 0.257$$
$$\text{log. } 3 = 0.477 \times 0.855 = 0.408$$
$$\text{log. } 4 = 0.602 \times 0.855 = 0.515,$$

or by any other convenient method of reducing the unit magnitude.

The logarithm of $0.0796 = \bar{2}.901 = -1.099$, and by placing the starting point of the v's above g a distance $1.099 \times 0.855 = 0.940$ on the scale of 20ths, thus adding -1.099, the logarithm of 0.0796, the reading on the v line is $0.0796\ d^{0.63}\ h^{0.54}$.

To introduce the factor, C, draw the C line parallel to the others at any suitable place between the v line and the h line. Draw the V line midway between the v line and the C line, as in Fig. 18.

From the point, 1, on the v scale, draw a line across the v, V, and C lines at any convenient angle, in order to locate the "1" points of the scales about to be plotted. Using the same unit as for v, lay off on the C line the logarithms of 1.1, 1.2, 1.3, and 1.4 above 1 and the logarithms of 0.9, 0.8, etc., below it. If the logarithms on the V line were now laid off with the same unit as those on the v and C lines, the reading at the crossing of any line, $a\ b$, would be the number corresponding to $\frac{1}{2}$ log. $v + \frac{1}{2}$ log. C.

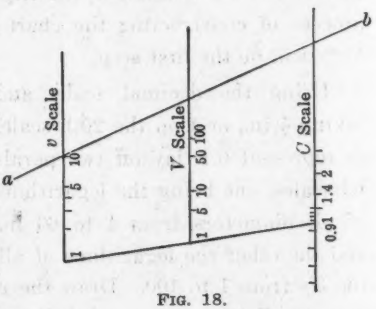

FIG. 18.

Therefore we make the V scale one-half as large as the other two, that is, with a unit of ($\frac{1}{4}$ in. $\times$ 0.855), which will give the product, $v\,C$, as required.

It is apparent that no divisions are required on the v line after the starting points for the V and C scales are drawn. Therefore it is left blank in the completed chart, Fig. 16, and marked "Line P" for reference.

In order to make the chart of greater use, it will be well to introduce another scale giving Q, the quantity discharged.

If Q = discharge, in cubic feet per second;
d = diameter, in inches;
V = velocity, in feet per second;
$Q = 0.00545 d^2 V$.

The d scale was plotted with a unit of $\frac{1}{2}$ in. to 0.1. Therefore it will serve for log. (d^2) with a unit of $\frac{1}{4}$ in. to 0.1. The V scale is made with a unit of ($\frac{1}{4}$ in. $\times$ 0.855), as shown on Fig. 19.

If we place the Q line between the d and V lines, as shown, the distance, $f\,g = n \times$ log. (d^2) + (1 — n) $\times$ 0.855 log. V, and if $n = (1 - n) \times 0.855$,

$$n = 0.462$$

Then $$f\,g = 0.462 \text{ log. } (d^2) + 0.462 \text{ log. } V.$$

If the Q scale were now laid off from g with a unit of ($\frac{1}{4}$ in. $\times$ 0.462), the reading at f would be the number corresponding to log. d^2 + log. V.

Log. 0.00545 = $\bar{3}.7364$ = —2.2636, and if we place the "1" of the Q scale above g a distance, $2.2636 \times 0.462 = 1.045$ on the 40th scale ($\frac{1}{4}$ in. representing 0.1), thus adding log. 0.00545, the reading at the intersection of a b will give $0.00545\ d^2\ V$, as required.

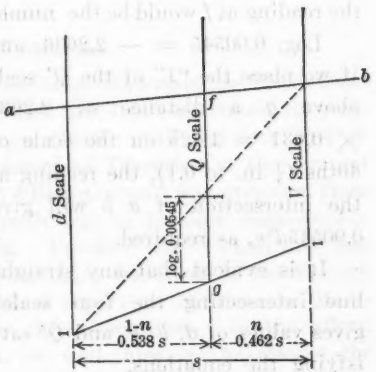

FIG. 19.

Assuming d and h to be known, and a value of C selected according to the condition of the pipe, place a straight-edge so as to connect d and h, and mark its intersection on "Line P". Similarly, connect the point just marked with the given C and at the intersection on the V line read the value of V. Then connect this V with the given d, and at the intersection on the Q line read Q in cubic feet per second.

It is evident that, by a suitable modification of the process described, either of the four quantities, d, h, V, or C, may be obtained when the other three are given.

As C is usually assumed at a round figure, multiplication or division by it is so simple that some might prefer a chart based on

the value 100 for this coefficient. The chart, Fig. 15, is constructed in this way, as follows:

Lay off the d, h, and v scales as described. The v scale will have its subdivisions completed and will occupy the position of "Line P" in the chart, Fig. 16.

The subdivisions on the d line represent log. (d^2) with a unit of $\frac{1}{4}$ in., and those on the v line represent log. v with a unit of ($\frac{1}{2}$ in. $\times$ 0.855), equivalent to $\frac{1}{4}$ in. $\times$ 1.71.

If we place the Q' line as shown in Fig. 20, the distance,

$$f\,g = m \text{ log. } (d^2) + (1 - m) \times 1.71 \text{ log. } v;$$

and if $m = (1 - m) \times 1.71$, $m = 0.631$.

Then $$f\,g = 0.631 \text{ log. } (d^2) + 0.631 \text{ log. } v.$$

If the Q' scale were laid off from g with a unit of ($\frac{1}{4}$ in. $\times$ 0.631), the reading at f would be the number corresponding to log. (d^2) + log. v.

Log. 0.00545 = — 2.2636, and if we place the "1" of the Q' scale above g a distance of 2.2636 $\times$ 0.631 = 1.428 on the scale of 40ths ($\frac{1}{4}$ in. to 0.1), the reading at the intersection of a b will give $0.00545d^2v$, as required.

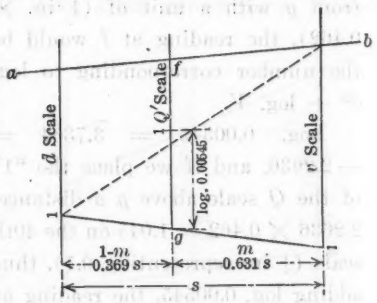

FIG. 20.

It is evident that any straight line intersecting the four scales gives values of d, h, v, and Q' satisfying the equations,

$$v = 100 \times 0.000796\, d^{0.63} h^{0.54},$$

and $$Q' = 0.00545 d^2 v.$$

By means of the "conversion scale", cubic feet per second may be read off at once, in millions of gallons per day.

The broken lines drawn on the charts, Figs. 15 and 16, show that when $d = 30$ in., $h = 33$ ft., and $C = 82$, the formula gives $V = 3.7$ and $Q = 18$ cu. ft. per sec. Also when $d = 30$ in. and $h = 33$ ft., $v = 4.5$ and $Q' = 22$ cu. ft. per sec.

AMERICAN SOCIETY OF CIVIL ENGINEERS

INSTITUTED 1852

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

PROGRESS REPORT OF THE SPECIAL COMMITTEE ON MATERIALS FOR ROAD CONSTRUCTION AND ON STANDARDS FOR THEIR TEST AND USE.*

To the American Society of Civil Engineers,

Your Special Committee on "Bituminous Materials for Road Construction, and on Standards for Their Test and Use", continued its work as such since its report of a year ago (1913) until the first part of June, 1914, when, by action of the Board of Direction at the Annual Convention of the Society, the word "Bituminous" was stricken from the title of the Committee. The result was to broaden considerably the field of the Committee's work. Further, the Committee has become aware of an expectation among many members of the Society that something in the nature of a final report on Bituminous Materials would shortly be presented by this Committee. In the effort, therefore, to meet this expectation, as well, also, as to release the Committee for its work in the broadened field of its action, the attempt is now made to present a comprehensive report, and one as nearly final as may be, under all the circumstances, on "Bituminous Materials Used in Road Construction, and on Standards for Their Test and Use".

It should be recognized that many points in reference to these materials are as yet unsettled, and are improbable of early settlement, because of the further investigations necessary to determine certain facts, or because of the insufficient time that has elapsed since certain investigations were begun in order to establish the facts. Under the existing arrangements, and in the manner proposed by the Committee, the latter will report from time to time any additional conclusions it may reach, on this particular subject, which it believes to be of value to the Society.

* To be Presented to the Annual Meeting, January 20th, 1915.

Since the publication of the Report of the Committee for 1913, some criticisms of it, or of the expressions used, have appeared. The Committee has considered these criticisms carefully, and has taken them into account in preparing this report.

Since June, 1914, the Committee has considered the scope of its work as your Special Committee on "Materials for Road Construction, and on Standards for Their Test and Use", but has concluded that a Semi-final Report on the "Bituminous Materials" should be prepared for presentation to the Society before it should undertake the investigations and collection of data necessary for a Progress Report on "Materials Other than Bituminous". The Committee therefore submits the following:

SEMI-FINAL REPORT ON BITUMINOUS MATERIALS USED IN ROAD-MAKING AND MAINTENANCE, WITH STANDARDS FOR THEIR TEST AND USE.

For more than 50 years, the use of Bituminous Materials of various kinds has prevailed in highway work to a greater or less extent in the United States, and for a longer period in some other countries. Except in the cases of a few materials, this use, until within 10 years or less, had been marked by the variety of materials used, the variety of methods of use, the variety of results secured, the lack of standards for materials, methods, and results, and the lack of appreciable advance in the science and art underlying the results.

In the exceptions referred to, which are meant to include the sheet-asphalt and certain bituminous concrete pavements, it may be said that progress had been steadily—if somewhat slowly—made in the sheet-asphalt work, and that the development of the bituminous concrete pavement rapidly advanced the science and art of bituminous pavements generally.

However, even including both these cases, as late as 6 years ago (1909) standards for materials were lamentably lacking. It was then customary, even where the specifications were otherwise all that could be expected, to describe the bituminous material by its trade name or as "equal to" a particular brand of fairly well-known character. Highway authorities generally knew little or nothing as regards means of identification of bituminous materials—even the asphalts coming under this statement—and no considerable agreement existed among engineers or chemists connected with highway work as to the analyses and tests desirable to be made on either the better known asphalts or on the newer materials offered for use. A suggestion then made, to the effect that bituminous materials could and should be purchased under specifications which would describe their essential characteristics, met with discouragement and even ridicule from many quarters. However, in 1909, your Board of Direction received and acted on

the suggestion that a Special Committee be appointed on "Bituminous Materials for Road Construction, and on Standards for Their Test and Use", and in May, 1909, appointed such a Committee.

It should be realized that, although European engineers have been constructing and maintaining bituminous pavements since the middle of the Nineteenth Century, your Board has authorized the first systematic and comprehensive work which has been undertaken in the endeavor to place the use of bituminous materials in highway work on a scientific basis.

The Committee, recognizing the diversity in both form and character of the available information on the subject, immediately set about collecting and co-ordinating such facts as might be obtained and securing additional information on uniform lines which seemed to it suitable. To this end, your Committee prepared blanks for the purpose of recording uniformly such exact information as apparently was desirable of collection from many sources, and distributed these forms widely, requesting that they be used for forwarding to the Committee the facts concerning the use of bituminous materials in construction. Later, the Committee prepared and distributed similar forms for data concerning the use of bituminous materials in maintenance work. The Committee regrets having to record a less generous response to its requests for information than has been hoped for. The Permanent International Association of Road Congresses printed in full the forms prepared by your Committee, and distributed them, in special pamphlet form, to the members of the Second International Road Congress held at Brussels, Belgium, in 1910. A complete revision of these forms has recently been made by the Committee, and the old and revised forms are attached to this report as Appendices A and B, respectively. The Analyses and Tests now recommended will be found in Appendix C.

The Committee made the effort to include in its schedules the points that seemed important to others of recognized experience in such matters; to adopt, as far as practicable, methods already standardized; and to make only such changes in ordinary methods as seemed to the Committee to be necessary for accuracy or improvement. To some extent, new methods, analyses, and tests, had to be suggested by the Committee, and the latter acted in these cases only after careful consideration and after conferring with many interested parties, including the manufacturers of such materials.

The investigations and correspondence of the Committee revealed such a variety of opinions concerning bituminous materials and their use in highway work that, not only was the action of your Board of Direction in creating the Special Committee supported, but also the Committee was moved to arrange with the Board of Direction for an opportunity to have such matters presented and discussed.

These arrangements resulted in special meetings of the Society being held just after the Annual Meetings of 1911, 1912, 1913, and 1914 (in 1910 an informal meeting under the auspices of the Committee was similarly held, but no special meeting of the Society itself, as in the later years). Through these meetings the interest of highway authorities was aroused and developed, and the papers that were presented, with the discussion thereon, undoubtedly did much to further the efforts of the Committee in its work as well as to advance the knowledge of highway matters generally.

In 1912, the Committee felt able to submit some conclusions unanimously agreed upon by its members. There were others that were strongly supported in the Committee, but which were withheld because of the apparent wisdom of acting conservatively in view of the rather small number voting. In this Report (January, 1912) the Committee also recommended that the attention of all interested be especially directed during the ensuing year to certain details of use, for the purpose of securing a consensus of opinion based on facts concerning these points, and that the definition of two terms of common use be adopted.

In 1913, the Committee again submitted a progress report, with some conclusions on various points, and recommended the adoption of the definition of another term of growing general use.

In 1914 (under date of November 15th, 1913) the Committee submitted a report of progress, which also summarized its earlier conclusions and collected all the latter in one place for the sake of easy reference and convenience. In this Report were included a number of new conclusions of the Committee (or original expressions of conclusions not before expressed though perhaps quite generally understood and accepted), and more than one hundred terms with their definitions, as recommended for adoption by the Committee.

As previously referred to, and for various reasons, it has seemed wise to the Committee to act conservatively in presenting conclusions to the Society. As your Board of Direction, however, early in 1914, added three new members to the original Committee of four, it has been possible to accomplish more results during 1914, especially in view of the ripening fruit of the earlier work of the original Committee, and it seems probable that such will also be the case for the near future at least.

At the present time it may be said that a number of important questions concerning the use of bituminous materials in highway work are desirable of investigation or of solution. Some investigations have been begun, but, as yet, have not been concluded successfully mainly because of lack of sufficient time for the proof of certain principles. Other investigations should be begun and pursued under such a variety of conditions as will render the conclusions of general

value. As the Committee has before stated (in its Report dated January, 1912), it believes "that, in order to solve many of the problems of construction and maintenance, it is more necessary to have at hand physical data recorded along uniform lines for a relatively short period than to prove the correctness of certain fine theoretical points", and, therefore, it again urges resistance to a tendency, apparent in some instances, to ignore the opportunity offered by the Committee for collaboration, which would result in mutual benefit, and deprecates any tendency to return to the former chaotic conditions which would ensue from individual, non-concurrent effort.

Of the investigations above mentioned as begun, but as yet unfinished, the following may be mentioned as important and worthy of conclusion:

(1) The effects of various kinds of earth or soil on bituminous carpets under known conditions of traffic;
(2) The efficiency of the use of asphaltic oils for surface treatments on gravel and broken stone roadways;
(3) The desirable analyses and tests to be made on bituminous materials for known conditions of use;
(4) The standardization of a determination and expression of the consistency of bituminous materials which preferably may permit of its use on all the wide range of such materials, from liquid to solid, and of the inter-relation existing in certain, if not in all, cases;
(5) The causes of the formation of waves or corrugations in bituminous surfaces and pavements;
(6) The use of a volatile flux instead of the application of heat for the purpose of rendering the bituminous material or cement sufficiently fluid for use under any method;
(7) The maximum quantity of distillate coming over, up to 170° cent., from tars (as determined by the test proposed by the Committee) which may be properly allowed in a material under any known conditions of use and of traffic;
(8) The maximum and minimum quantities of free carbon that can be successfully allowed in tars under known conditions of other constituents of the tar, of climate, of traffic, and of methods of use;
(9) The advisability of incorporating in bituminous pavements, built by the penetration method, bituminous material in excess of the minimum quantity necessary for the production of satisfactory results;
(10) The relative efficiency of the various pressures used in the application of various grades and types of bituminous materials in the construction of bituminous surfaces and bituminous pavements built by the penetration method;

(11) The variable allowable limits of the percentage of bitumen in bituminous concrete mixtures, dependent on the kind and sizes of the component parts of the mineral aggregates;

(12) The allowable maximum penetrations of various types of asphalt cements when such cements are used in bituminous concrete pavements which must be open to traffic shortly after being laid;

(13) The efficiency of bituminous concrete pavements constructed with a number of courses composed of different sizes of broken stone;

(14) The allowable minimum atmospheric temperatures under which it is practicable to secure the desired compressions of bituminous concrete mixtures composed of various grades of different types of bituminous cements and different kinds of mineral aggregates; and

(15) The use of "seal coats" on bituminous pavements under stated conditions.

Of the investigations before mentioned as important and worthy of commencement and prosecution, the following may be noted:

(1) The establishment of standards for recording, compiling, and reporting costs of results secured in highway work;

(2) The establishment of standard forms of specifications for the various kinds of bituminous surfaces and pavements ordinarily used, including the bituminous materials therefor;

(3) The devising of standards for recording and compiling traffic censuses, especially to the end that comparisons of traffic can be made readily and with relative accuracy; and

(4) The establishment and expression of any relation between the traffic and the life or cost of any bituminous surface or pavement.

The Committee now submits its conclusions on Bituminous Materials with the new or the modified forms of its earlier reported conclusions in heavy type, as follows:

General.—The Committee deplores the tendency, apparent in some quarters, to devote time and energy for the discovery of "The most satisfactory road surface", and expresses its conviction that there is no such thing as a "panacea" for all highway ills. It believes that, with the development of highway work, it should be constantly more apparent that one of the greatest problems to be solved by highway engineers is the proper selection of the particular material and form of construction to be used, which most efficiently meet the conditions of any particular case, and that progress will be hastened by complete recognition of this fact.

Most materials and methods of use of bituminous materials have their values, and the real problems are the determination of these values and of their adaptability or fitness to meet the conditions of any case properly.

A bituminous surface or pavement properly designed for carrying light motor vehicles may not be the one best adapted to horse-drawn vehicles, and one which is efficient for light horse-drawn vehicles may be most seriously injured by motor vehicles. A solution of the problem of the proper design and construction of a roadway for mixed traffic is, under any local conditions on which the solution ultimately depends, difficult, though facts are accumulating which may finally permit this solution.

It is still desirable to record the characteristics and details (including cost figures) of use of bituminous materials, and great concordance in so doing is most necessary.

Census of Traffic.—Your Committee desires to emphasize the fact that experience has demonstrated the value of a traffic census taken both preliminary and subsequent to the construction of a highway.

The traffic census should be considered one of the most important variable factors in the solution of that important problem, the selection of that type of construction best suited to local conditions considered from the standpoints of both economy and efficiency. In connection with the census returns on any highway should be considered the traffic on cross and parallel highways and the effect of improvement of these highways on the traffic of the highway under construction.

It should not be taken for granted that the bald return of a traffic census should be the sole basis of the selection of the type of construction, but it should be considered a guide in determining the value of the type adopted.

Where motor traffic forms a considerable proportion of the total traffic likely to use a highway, the unit width of traffic lines should be considered as 9 or 10 ft., instead of 7 or 8 ft., as heretofore, because of the greater clearance required for the safe passing of the units of such traffic.

In considering the effect of traffic and its relation to the design and cost of maintenance, it is necessary to take into account the speed as well as the weight of the vehicles.

In view of the recent constant and rapid increase of traffic on the highways, both in number of vehicles and in wheel loads, it will be in the interests of economy for designs of highways to be made with proper consideration of further increases.

Collection and Standardization of Cost Data.—In the work of the Committee, it has become apparent that conclusions may necessitate the use of cost data, recorded along uniform lines. It seems to be

urgent that standards for arriving at costs be established and generally adopted as promptly as possible. Your Committee therefore recommends to the attention of the Profession this important feature of engineering work, with the hope that uniform methods will be generally adopted at an early date for reporting Costs of Construction and of Maintenance.

The Committee believes that, along the lines of standardization in reporting cost data and for general benefit, it would be advisable for highway departments, in making their regular periodic reports, to adopt a tabular form for presenting their records of the costs of their construction work, which should include data or figures in columns as follows:

Identification of Work;
Description (Width, Thickness, and Material or Form of Construction);
Length;
Area of Bituminous Pavement or Surface;

Construction Expenditures for
- **Preliminary surveys and plans;**
- **Grading;**
- **Surfacing;**
- **Bridges and culverts;**
- **Under-drains;**
- **Superintendence and inspection;**
- **Miscellaneous;**

Total of above;
Rights of Way and Damages;
Total Construction and Rights of Way and Damages;
Administration, Legal and General Engineering Expenses;
Total Expenditures and Overhead Expenses;

For the maintenance expenditures there should be a tabular form showing, in columns:

Identification of work;
Length;
Area;

Maintenance Expenditures for
- **Labor;**
- **Material;**
- **Hire of teams and equipment;**
- **Inspection and superintendence;**
- **Miscellaneous;**

Total of above;
Administration, Legal and General Engineering Expenses;
Total Cost of Maintenance.

Each table, of course, should carry such foot-notes or text as might be necessary to supply the further information as to unusual rates of pay or other conditions advisable to be shown.

In compiling costs of any item of work done, the Committee believes that it would be advisable and of great public benefit if, hereafter, all such figures be compiled whenever practicable on the following basis:

Total Cost to be Reported per Unit for
- **Cost for materials delivered on site of work;**
- **Cost for labor and teams placing materials;**
- **Cost for machinery engaged in placing materials and in finishing the work;**
- **Cost for inspection and superintendence;**
- **Cost for general overhead charges.**

In foot-notes or in the text such statements as may seem desirable in any case should be made concerning rates of pay, conditions, and circumstances.

Construction—General.—Your Committee is agreed that:

The use of any form of a bituminous pavement or bituminous surface does not preclude the necessity for the construction of a well-drained, thoroughly compacted, and adequate foundation. In fact, such improvement of the highway frequently attracts heavier traffic and thus increases the stresses on the sub-grade.

Within certain limits of traffic, the proper use of bituminous material should effect economy in the expenditures for the cleaning and maintenance.

The proper treatment of a broken stone, gravel, shell, or slag roadway with bituminous material, for the purpose of eliminating the so-called dust nuisance, will at the same time render even the best of such roadways more efficient for sustaining traffic, and such treatment with bituminous materials is usually preferable and more economical than sprinkling with water, or the use of hygroscopic salts.

An objectionable slipperiness of bituminous pavements or bituminous surfaces may be decreased or prevented by proper precautions during construction or by proper treatment thereafter.

The crown generally used in the construction of broken stone roadways is excessive when bituminous materials are used, and a crown of even 1/2 in. per ft. should be avoided when a lesser crown can be secured without detriment to the surface drainage.

Construction—Materials.—Your Committee is agreed that:

For the present, at least, whenever comprehensive specifications are to be prepared so as to admit a variety of types of bituminous materials, separate specifications as may be necessary should be prepared for each type.

Where bituminous pavements are laid, the edges should be protected and a sudden transition from the pavement to any softer shoulder material avoided by means of cement concrete or other

edgings and such reinforcement of the shoulder material as may be necessary.

The character of the stone to be used may influence the choice of the bituminous material.

Whatever method may be used in any case, it is essential, as in water-bound construction, that a suitable quality of road metal be used.

By proper selection and use of the bituminous material, injury to property and deleterious effects upon animal and vegetable life may be avoided, and also considerable hygienic advantage may result from the use of such materials on the highways.

The maximum quantity of distillate up to 170° cent. allowable in tars depends on the proportions of the other fractions in a tar, and on the conditions of use of the tar, and possibly on the conditions on the road surface after its construction, or on some other facts.

Construction—Methods.— **Your Committee wishes to emphasize the fact that the selection of the method of construction to be used in a given case will depend on the results of preliminary investigations, and that the recent and imminent development of, and the availability of, mechanical appliances, should affect the decision to a great degree.**

Whatever method of construction is selected, the use of a bituminous material by no means justifies any lack of care in the ordinary details to be followed, but rather increases the need for thoroughness and skilled supervision.

The main principles underlying perfection in water-bound roads remain in full force when such roads are treated with bituminous material.

In all uses of bituminous materials in highway work, the use of proper machinery is preferable, wherever conditions make such practicable in any part of the process, to the use of hand labor.

The use or omission of a seal coat on bituminous pavements is dependent on one or more of the following points:

(*a*) The character of the bituminous material used,

(*b*) The method of construction,

(*c*) The density and quality of the work done, and

(*d*) The kind and amount of traffic to be expected on the completed highway.

The length of time that the finished pavement should be closed to traffic varies from a few hours to several days, dependent on the character of the bituminous material used, the method, and on climatic and other local conditions.

Construction—Mixing Methods.—Your Committee is agreed that:

Where the character of the traffic justifies the use of a bituminous concrete pavement, it also demands a correspondingly strong foundation.

The quantity of bituminous material to be used in any case will depend on the peculiar conditions of that case, such as the kind of road metal and of bituminous material, the character of the aggregate, the climatic conditions, etc.

The fluidity of the bituminous materials used should be sufficient to insure a proper coating of the mineral particles, and such fluidity may be obtained by heating—provided the degree of heat is not excessive or sufficient to injure the bituminous materials, and is reached through proper methods.

The bituminous material should possess adhesive and cohesive qualities sufficient to enable it to perform its purposes properly under the conditions of any case, and it should not be of a greasy character.

The adhesiveness, cohesiveness, resiliency, and elasticity of the material should have the greatest possible permanence.

The success of results depends largely on the use of proper sizes of the particles and on securing a proper density of the mixture for the local conditions.

The character of the mineral aggregate to be used may be controlled by local conditions, but the best results can only be obtained by the use of the best materials. Excessive sizes, or excessive variations in the size of the mineral particles, should be avoided, and the utmost care must be taken to avoid the segregation of particles of different sizes.

Mixing machines should be used, and hand-mixing methods should be avoided wherever practicable.

The success of results is greatly dependent on the degree of uniformity obtained in spreading the mixture and on the proper rolling and compacting of the mixture. Too heavy a roller should not be used.

Care should be taken in prescribing or laying any seal coat that invitation or excuse is not given for inferior prior work and its concealment by such a seal coat.

The use of fine sand on top of bituminous concrete is open to grave objections, and the use of clean stone chips or small gravel free from particles that will pass through a 10-mesh sieve seems preferable.

Trap rock in sizes greater than that passing a 2-in. screen should be used with caution in the construction of the upper course unless voids of the same are properly reduced, because of the likelihood of the individual stones to rock under traffic.

In the use of a heated aggregate for the construction of a bituminous concrete pavement non-uniformity or excess in the heating of stone should be avoided.

Construction—Penetration Method.—Your Committee is agreed that:

An important factor for successful results is the proper compaction by rolling of the road metal before the spreading of the bituminous material.

The use of pressure distributors is to be preferred to hand-pouring applications.

The bituminous material should be sufficiently, but not excessively, fluid when used.

The bituminous material should be sufficiently adhesive and cohesive to carry out the purpose for which it is used, and should not be of a greasy character.

The essential characteristics of a bituminous material, such as adhesiveness, cohesiveness, resiliency, and elasticity, should have the greatest possible permanence.

The needed penetration of the material into the rolled stone is had when the bituminous material reaches to the bottom of the average sized stone in the course penetrated.

With the use of materials susceptible to heat, or fairly so, or otherwise of considerable fluidity during application or for a reasonable period thereafter at normal temperatures, the application of the bituminous material to the rolled stone can well be stopped on a line parallel to and within the edges of the stone, and reliance may be had for this border of the macadam becoming properly bound by the flowing of the bituminous material into it under heat and traffic. With the use of materials having the opposite characteristics, the application of the bituminous materials should be made fully to the edges of the rolled stone.

Present indications are to the effect that the use of bituminous materials in quantities of more than 2 1/2 gal. per sq. yd., where the upper course of the macadam is to be 3 in. in thickness after compaction, is inadvisable under the penetration method, although sufficient data do not yet seem to be at hand to determine exactly in any case the value or possible advantage of using bituminous material in excess during construction in order to furnish a sort of reservoir by means of which to prolong the life of the surface of the bituminous pavement.

The use of fine sand on top of the bituminous material is open to grave objections, and clean stone chips or small gravel, free from particles that will pass through a 10-mesh sieve, is preferable.

Construction—Surface Treatments.—Your Committee is agreed that:

The success of surface applications is proportionate to the adhesion obtained by the bituminous material to the old roadway surface, and such degree of cleanliness of the latter must be had,

by means of sweeping or other methods, as will insure a proper degree of adhesion.

The roadway surface should be dry when the bituminous material is applied.

Whether or not the application of bituminous material is to be followed by an application of mineral material, and the length of time to be allowed to elapse between the application of bituminous material and a subsequent application of mineral material, depends on local conditions and on the character and amount of the bituminous material used.

To be successful, a carpet must be able to absorb shocks sufficiently to prevent disintegration, by such shocks, of the surface to which it is applied.

The bituminous material should be sufficiently, but not excessively, fluid when used.

The bituminous material should be sufficiently adhesive and cohesive to carry out the purpose for which it is used under any conditions, and should not be of a greasy character.

The adhesiveness, cohesiveness, resiliency, and elasticity of a bituminous material used for this purpose should be of the greatest possible permanence.

The application of bituminous materials should in all cases be carried well over the outside edges of the rolled metal and on the shoulder far enough to protect the edges of the metaled surface.

The use of fine sand on top of the bituminous material is open to grave objections, the use of clean stone chips or small gravel, free from particles that will pass through a 10-mesh sieve, being generally preferable.

Attempts to construct and maintain by bituminous surface treatments a carpet of a greater total thickness than ½ in. have generally been unsuccessful, and in the construction of a successful carpet of a total thickness approximating ½ in. the materials should be applied in layers, at intervals, rather than by the construction of the total thickness in one application.

The quantity of bituminous material to be used depends on the local conditions in any particular case, but excess in any application is to be avoided, as a deficiency may be corrected by a subsequent application, whereas an excess in any application is difficult, if not impossible, of correction.

The success of results depends first on the condition of the surface to which the treatment is applied. Even the best surface treatment cannot correct defects in the original surface, though it may reduce or modify them.

The application of the bituminous material by means of a pressure distributor is, wherever practicable, preferable to gravity or hand-pouring methods.

Considerable evidence seems to make undesirable the presence of free carbon beyond a maximum, dependent on the distillate between 170° and 300° cent., in tars for superficial treatments, in order at least to avoid brittleness at low temperatures.

The maximum quantity of residue allowable in an asphaltic oil used for superficial treatment should be as great as permitted by the physical conditions of its use, subject to certain limits in the penetration of this residue, and such limits in penetration should be

A minimum which will ensure against undesirable hardness or slipperiness under travel at low temperatures,

A maximum which will ensure against undesirable softness or lack of body at the highest temperatures to be expected after use on the road.

Maintenance and Repairs.—Your Committee is agreed that:

Repairs to bituminous pavements and bituminous surfaces should be made so as to secure immediately the greatest possible homogeneity.

It is even more necessary than with many other types of construction to carry out repairs on bituminous pavements and bituminous surfaces immediately the desirability for them appears.

Nomenclature.—Your Committee wishes to advise strongly the discontinuance of the use of the terms "liquid asphalt" and "asphaltic contents", as these terms are meaningless in many cases, and unnecessary when proper tests, such as are suggested by your Committee, are used.

For the sake of uniformity and clearness, the Committee recommends that the following lists of terms of frequent use in expressions relating to highway work be recognized as having the meanings set forth in the list, unless otherwise definitely stated at any time by a user of such term or terms. The Committee further recommends, that new terms or phrases, coined with the idea of expressing delicate shades of meaning through the medium of one or two words rather than by longer expressions, be suggested or used only after full, careful, and conservative consideration for the sake of avoiding to the utmost further confusion in the use of terms.

In the list given will be found some terms and definitions adopted by the American Society for Testing Materials noted thus *, others by the American Reporters on Communication No. 10 at the Third International Road Congress, designated thus †, and other terms and definitions which have been proposed by the Committee on "Standard Tests for Road Materials" (Committee D 4) of the American Society for Testing Materials, which have been indicated thus ‡. The Committee wishes to acknowledge here its obligations for suggestions thus reaching it.

DEFINITIONS.

***Aggregate.*—The mineral material, such as sand, gravel, shells, slag, or broken stone, or combinations thereof, with which the cement or the bituminous material is mixed to form a mortar or concrete. Fine aggregate may be considered as the mineral inert material which will pass a 1/4-in. screen, and coarse aggregate the material which will not pass a 1/4-in. screen.**

Asphalt.—† Solid or semi-solid native bitumens, solid or semi-solid bitumens obtained by refining petroleums, or solid or semi-solid bitumens which are combinations of the bitumens mentioned with petroleums or derivatives thereof, which melt on the application of heat, and which consist of a mixture of hydrocarbons and their derivatives of complex structure, largely cyclic and bridge compounds.

***Asphalt Block Pavement.*—One having a wearing course of previously prepared blocks of asphaltic concrete.**

***Asphalt Cement.*—A fluxed or unfluxed asphaltic material, especially prepared as to quality and consistency, suitable for direct use in the manufacture of asphaltic pavements, and having a penetration of between 5 and 250.**

Asphaltenes.—† The components of the bitumen in petroleum, petroleum products, malthas, asphalt cements, and solid native bitumens, which are soluble in carbon disulphide, but insoluble in paraffin naphthas.

***Asphaltic.*—Similar to, or essentially composed of, asphalt.**

Base.—Artificial foundation.

Binder.—(1) A foreign or fine material introduced into the mineral portion of the wearing surface for the purpose of assisting the road metal to retain its integrity under stress, as well as, perhaps, to aid in its first construction. (2) The course, in a sheet-asphalt pavement, frequently used between the concrete foundation and the sheet-asphalt mixture of graded sand and asphalt cement.

Bitumen.—* A mixture of native or pyrogenous hydrocarbons and their non-metallic derivatives, which may be gases, liquids, viscous liquids, or solids, and which are soluble in carbon disulphide.

***Bituminous Cement.*—A bituminous material suitable for use as a binder having cementing qualities which are dependent mainly on its bituminous character.**

Bituminous Concrete Pavement.—One composed of stone, gravel, sand, shell, or slag, or combinations thereof, and bituminous materials incorporated together by mixing methods.

***Bituminous Macadam Pavement.*—One having a wearing course of macadam with the interstices filled by penetration methods with a bituminous binder.**

***Bituminous Material.*—Material containing bitumen as an essential constituent.**

***Liquid Bituminous Material.*—‡ Bituminous material showing a penetration at normal temperature under a load of 50 grammes applied for 1 sec. of more than 350.**

***Semi-Solid Bituminous Material.*—‡ Bituminous material showing a penetration at normal temperature under a load of 100 grammes applied for 5 sec. of more than 10, and under a load of 50 grammes applied for 1 sec. of not more than 350.**

***Solid Bituminous Material.*—‡ Bituminous material showing a penetration at normal temperature under a load of 100 grammes applied for 5 sec. of not more than 10.**

Bituminous Pavement.—One composed of stone, gravel, sand, shell or slag, or combinations thereof, and bituminous materials incorporated together.

Bituminous Surface.—A superficial coat of bituminous material with or without the addition of stone or slag chips, gravel, sand, or material of similar character.

Blanket.—See "Carpet".

Bleeding.—The exudation of bituminous material on the roadway surface after construction.

Blown Petroleums.—† Semi-solid or solid products produced primarily by the action of air upon originally fluid native bitumens which are heated during the blowing process.

***Bond.*—The combined action of inertia, friction, and of the forces of adhesion and cohesion which helps the separate particles composing a crust or pavement to resist separation under stress. Mechanical bond is the bond produced almost wholly, in a well-built broken-stone macadam road, by the interlocking of angular fragments of stone and the subsequent filling of the remaining interstices with the finer particles.**

Bound.—Bonded.

Water-Bound.—Bonded with the aid of water.

Bituminous Bound.—Bonded with the aid of bituminous material.

***Brick Pavement.*—One having a wearing course of paving bricks or blocks.**

Bridge.—A structure for the purpose of carrying traffic over a gap in the road-bed measuring 10 ft. or more in the clear span.

Camber of a Road.—See "Crown".

Camber of a Bridge.—The rise of its center above a straight line through its ends.

Carbenes.—† The components of the bitumen in petroleums, petroleum products, malthas, asphalt cements, and solid native bitumens, which are soluble in carbon disulphide, but insoluble in carbon tetrachloride.

Carpet.—**A bituminous surface of appreciable thickness, generally formed on top of a roadway by the application of one or more coats of bituminous material with gravel, sand, or stone chips added.**

Cement.—**An adhesive substance used for uniting particles of other materials to each other. Ordinarily applied only to calcined "cement rock", or to artificially prepared, calcined, and ground mixtures of limestone and silicious materials. Sometimes used to designate bituminous binder used in bituminous pavements, when the expression "bituminous cement" (q. v.) is understood to be meant.**

Cement-Concrete.—**An intimate mixture of gravel, shell, slag, or broken stone particles with certain proportions of sand or similar material, cement, and water, made previous to placing.**

Cement-Concrete Pavement.—**One having a wearing course of hydraulic cement concrete.**

Cemented.—**Bonded. Referring to water-bound macadam, the term "cemented" is used to designate that condition existing when, after rolling the stone forming the crust, the remaining voids have been filled with the finer sizes, and the stone dust or "flour" has, under the action of water, taken a "set", as does cement itself.**

Chips.—**Small angular fragments of stone containing no dust.**

Clay.—**Finely divided earth, generally silicious and aluminous, which will pass a 200-mesh sieve. Also see "Gravel".**

Coal-Tar.—† The mixture of hydrocarbon distillates, mostly unsaturated ring compounds, produced in the destructive distillation of coal.

Coat.—**See "Carpet". (1) The total result of one or more single surface applications. (2) To apply a coat.**

Coke-Oven Tar.—† Coal-tar produced in by-product coke ovens in the manufacture of coke from bituminous coal.

Consistency.—‡ **The degree of solidity or fluidity of bituminous materials.**

Course.—**One or more layers of road metal spread and compacted separately for the formation of the road or pavement. Courses are usually referred to in the order of their laying as first course, second course, third course, etc. Also a single row of blocks in a pavement.**

Crown.—**The rise in cross-section from the lowest to the highest part of the finished roadway. It may be expressed either as so many inches (or tenths of a foot), or as a rate per foot of distance from side to center, *i. e.*, "the crown is 4 in.", or "the crown is 1/2 in. to the foot".**

Crusher Run.—The total unscreened product of a stone crusher.

Crusher-Run Stone.—**The product of a stone-crusher, unscreened except for the removal of the particles smaller than remaining on about a 1/4-in. screen.**

***Crust.*—That portion of a macadam or similar roadway above the foundation consisting of the road metal proper with its bonding agent or binder.**

Culvert.—A structure for the purpose of carrying traffic over a gap in the road-bed, measuring less than 10 ft. in clear span.

***Cut-Back Products.*—Petroleum, or tar residuums, which have been fluxed, each with its own or similar distillates.**

Dead Oils.—* Oils, with a density greater than water, which are distilled from tars.

Dehydrated Tars.—† Tars from which all water has been removed.

***Ditch.*—The open-side drain of a roadway, usually deep in proportion to its width, and unpaved.**

Drainage.—Provision for the disposition of water.

***Side-Drainage.*—That along the sides of the roadway.**

Sub- or Under-Drainage.—That below the surface.

***Surface Drainage.*—That on the roadway or ground surface.**

***V-Drainage.*—That provided by the construction of troughs in the sub-grade of the roadway, which troughs are like a "V", with flat sloping sides, and are filled with stone.**

***Dust.*—‡ Earth or other matter in fine, dry particles, so attenuated that they can be raised and carried by air currents. The product of the crusher passing through a fine sieve.**

***Dust Layer.*—Material applied to a roadway for temporarily preventing the formation or dispersion under traffic of distributable dust.**

***Earth Road.*—A roadway composed of natural earthy material.**

***Emulsion.*—A combination of water and oily material made miscible with water through the action of a saponifying or other agent.**

***Expansion Joint.*—A separation of the mass of a structure, usually in the form of a joint filled with elastic material, which will provide opportunity for slight movement in the structure.**

***Fat.*—Containing an excess. A fat asphalt mixture is one in which the asphalt cement is in excess and the excess is clearly apparent.**

***Filler.*—(1) Relatively fine material used to fill the voids in the aggregate. (2) Material used to fill the joints in a brick or block pavement.**

***Fixed Carbon.*—* The organic matter of the residual coke obtained upon burning hydrocarbon products in a covered vessel in the absence of free oxygen.**

***Flour.*—† Finely ground rocks or minerals pulverized to an impalpable product.**

Flush Coat.—See "Seal Coat".

Flushing.—(1) Completely filling the voids. (2) Washing a pavement with an excess of water.

Flux.—† Bitumens, generally liquid, used in combination with harder bitumens for the purpose of softening the latter.

Footway.—The portion of the highway devoted especially to pedestrians. A sidewalk.

Foundation.—The portion of the roadway below and supporting the crust or pavement.

Artificial Foundation.—That layer of the foundation especially placed on the sub-grade for the purpose of reinforcing the supporting power of the latter itself, and composed of material different from that of the sub-grade proper.

Free Carbon.—* In tars, organic matter which is insoluble in carbon disulphide.

Gas-House Coal-Tar.—† Coal-tar produced in gas-house retorts in the manufacture of illuminating gas from bituminous coal.

Grade.—(1) The profile of the center of the roadway, or its rate of rise or fall. (2) Elevation. (3) To establish a profile by cuts and fills or earthwork. (4) To arrange by sizes, broken stone, gravel, sand, or combinations of such materials.

Gravel.—Small stones or pebbles usually found in natural deposits more or less intermixed with sand, clay, etc., but in which mixture, the particles which will not pass a 10-mesh sieve predominate, gravel clay, gravel sand, clayey gravel, and sandy gravel indicate the varying proportions of the finer-sized particles. The differentiation between gravel, sand, silt, and clay should be made on the following basis:

Size of Particles.	*Names.*
Retained on a 10-mesh sieve	Gravel.
Passing a 10-mesh and held on a 200-mesh sieve	Sand.
Passing a 200-mesh sieve	Silt or Clay.

Pea Gravel.—Clean gravel the particles of which equal peas in size.

Grit.—Stone, slag chips, or small gravel free from finer material.

Gutter.—The artificially surfaced and generally shallow waterway provided usually at the sides of the roadway for carrying surface drainage. Occasionally used synonymously with "ditch", but incorrectly so, as "gutters" are always paved or otherwise surfaced, and ditches are not.

Haunches.—The sides or flanks of a roadway. Sometimes also called "quarters".

Highway.—The entire right of way devoted to public travel, including the sidewalks and other public spaces, if such exist.

Layer.—A course made in one application.

Loam.—Finely divided earthy material containing a considerable proportion of organic matter.

Macadam.—A road crust composed of stone or similar material broken into irregular angular fragments compacted together so as

to be interlocked and mechanically bound to the utmost possible extent.

***Mastic.*—A mixture of bituminous material and fine mineral matter suitably made for use in highway construction and for application in a heated condition.**

Mat.—† See "Carpet".

***Matrix.*—A composition or material forming a cushion, or binding the aggregate together.**

***Mesh.*—The square opening of a sieve.**

Metal.—See "Road-Metal".

***Mortar.*—A mixture of fine material such as sand, cement, and water or other liquid suitably proportioned and incorporated together for the purpose for which it is used.**

***Mush.*—A greasy mud sometimes found on bituminous crusts.**

***Normal Temperature.*—‡ In laboratory investigations, 25° cent. (77° Fahr.).**

Oil-Gas Tars.—Tars produced by cracking oil vapors in the manufacture of oil gas.

Patching.—Repairing or restoring small isolated areas in the surface of the metaled or paved portion of the highway.

***Palliative.*—A short-lived dust layer.**

***Pavement.*—The wearing course of the roadway or footway, when constructed with a cement or bituminous binder, or composed of blocks or slabs, together with any cushion or "binder" course.**

***Penetration.*—In laboratory investigations, the distance, expressed in tenths of a millimeter, entered a sample by a No. 2 cambric needle operated in a machine for the purpose and under known conditions of loading, time, and temperature. The degree of solidity of bituminous materials.**

In construction, the entrance of bituminous material into the interstices of the metal of the roadway.

Penetration Method.—The method of constructing a bituminous-macadam pavement by pouring or grouting the bituminous material into the upper course of the road metal before the binding of the latter has been completed.

***Pitch.*—† Solid residue produced in the evaporation or distillation of bitumens, the term being usually applied to residue obtained from tar.**

***Hard Pitch.*—Pitch showing a penetration of not more than ten.**

***Soft Pitch.*—Pitch showing a penetration of more than ten.**

***Straight-Run Pitch.*—‡ A pitch run in the initial process of distillation, to the consistency desired without subsequent fluxing.**

***Pocket.*—A hole or depression in the wearing course.**

***Pot-Hole.*—A hole extending below the wearing course.**

***Profile.*—A longitudinal section of a highway, generally taken along the center line.**

***Quarters.*—The four sections of equal width which, side by side, make up the total width of a roadway.**

***Raveling.*—The loosening of the metal composing the crust.**

Refined Tar.—† A tar freed from water by evaporation or distillation which is continued until the residue is of desired consistency, or a product produced by fluxing tar residuum with tar distillate.

Renewals.—Extensive repairs over practically the whole surface of the metaled or paved portion of the highway.

Repairs.—The restoration or mending of a considerable amount of the metaled or paved portion of the highway, but not usually of a majority of the surface area. More extensive than "Patching" but less so than "Renewals".

***Resurfacing.*—The renewal of the surface of the crust or pavement.**

***Road.*—A highway outside of an urban district.**

***Road-Bed.*—The natural foundation of a roadway.**

Road Metal.—Broken stone, gravel, slag, or similar material used in road and pavement construction and maintenance.

***Roadway.*—That portion of a highway particularly devoted to the use of vehicles.**

***Rock Asphalt.*—Sandstone or limestone naturally impregnated with asphalt.**

***Rock Asphalt Pavement.*—A wearing course composed of broken or pulverized rock asphalt with or without the addition of other bituminous materials.**

***Sand.*—Finely divided rock detritus the particles of which will pass a 10-mesh and be retained on a 200-mesh screen. Also see "Gravel".**

***Sand-Clay Road.*—A roadway composed of an intimate mixture of sand and clay.**

***Scarify.*—To loosen and disturb superficially.**

***Screen.*—In laboratory work an apparatus, in which the apertures are circular, for separating sizes of material.**

***Screenings.*—Broken rock of a size that will pass through a 1/2- to 3/4-in. screen, depending on the character of the stone.**

Seal Coat.—A final superficial application of bituminous material during construction to a bituminous pavement.

***Setting Up.*—The relatively quick change such as takes place in a bituminous material after its application to a roadway, indicated by its hardening after cooling and exposure to atmospheric and traffic conditions, as opposed to the slower changes later occurring gradually and almost imperceptibly.**

***Shaping.*—Trimming up and preparing a sub-grade preparatory to applying the first course of the road metal or artificial foundation.**

***Sheet-Asphalt Pavement.*—One having a wearing course composed of asphalt cement and sand of predetermined grading, with or without the addition of fine material, incorporated together by mixing methods.**

***Sheet Pavement.*—A pavement free from frequent joints such as would accompany small slabs or blocks, and which has an appreciable thickness (say, in excess of 1 in. on the average) for its wearing course.**

Shoulders.—The portion of the highway between the edges of the road metal or pavement and the gutters, slopes, or watercourses.

Side Drain.—See "Drainage".

Sidewalk.—The portion of the highway reserved for pedestrians.

***Sieve.*—In laboratory work an apparatus, in which the apertures are rectangular, for separating sizes of material.**

***Silt.*—Naturally deposited fine earthy material, which will pass a 200-mesh sieve. Also see "Gravel".**

***Spalls.*—Fragments broken off by a blow, irregular in shape, and of sufficient size to be comparable to the original mass.**

***Squegee.*—A tool with a rubber or leather edge for scraping or cleaning hard surfaces, or for spreading and distributing liquid material over and into the superficial interstices of roadways.**

***Squegee Coat.*—An application by means of the squegee.**

***Stone Block Pavement.*—One having a wearing course composed of stone blocks quite or nearly rectangular in shape.**

***Street.*—A highway in an urban district.**

Sub-Grade.—The upper surface of the native foundation on which is placed the road metal or the artificial foundation, in case the latter is provided.

Superficial Coat.—A light surface coat.

Surface Coat.—See "Carpet".

***Surfacing.*—(1) The crust or pavement. (2) Constructing a crust or pavement. (3) Finally finishing the surface of a roadway. (4) Treating the surface of a finished roadway with a bituminous material.**

***Surface Treatment.*—Treating the finished surface of a roadway with bituminous material.**

Tailings.—Stones which after going through the crusher do not pass through the largest openings of the screens.

***Tar.*—† Bitumen which yields pitch upon fractional distillation and which is produced as a distillate by the destructive distillation of bitumens, pyro-bitumens, or organic material.**

Telford.—Properly an artificial foundation advocated by Thomas Telford (1757-1820), and consisting of a pavement of stone about 8 in. thick, laid by hand, and closely packed and wedged together. The individual stones were desired to be about 16 sq. in. in section, and about 8 in. in length. They were set close together on the prepared

sub-grade, their longest dimension vertical and on their larger ends, their interstices chinked with smaller stones, and the whole rammed (or rolled) until firm and unyielding.

Telford Macadam.—Macadam with an artificial foundation of Telford.

Under-Drain.—See "Drainage".

***Up-Keep.*—Maintenance.**

V-Drain.—See "Drainage".

***Viscosity.*—The degree of fluidity of bituminous materials.**

***Volatile.*—Applied to those fractions of bituminous materials which will evaporate at climatic temperatures.**

***Water-Bound.*—Bound or bonded with the aid of water.**

Water-Gas Tars.—Tars produced by cracking oil vapors in the manufacture of carbureted water-gas.

***Wearing Coat.*—The superficial layer of the crust or pavement exposed to traffic.**

***Wearing Course.*—The course of the crust or pavement exposed to traffic.**

***Wood Block Pavement.*—One having a wearing course composed of wood paving blocks, generally rectangular in shape.**

Your Committee has carefully considered the advisability of presenting a progress report on "Materials Other than Bituminous". Owing to the time which it has been obliged to devote to the above report on "Bituminous Materials" it has been unable to consider any but the most general questions relating to other materials. Your Committee has been impressed with the fact that there is a wide divergence of opinion and of practice with respect to the use of such materials, but that it might attempt to present some standards and principles which are fairly well defined and quite generally accepted, and to suggest other matters which should receive attention and be made the subject of investigation by highway engineers. The majority of the Committee feels, however, that it should defer a progress report on "Materials Other than Bituminous" until it is able to secure more precise information and reach more definite conclusions.

The Committee wishes to express again its deep appreciation of the assistance rendered it by the Board of Direction and by your Secretary, Mr. Charles Warren Hunt, as well as by the members of the Society and others.

Very respectfully,

SPECIAL COMMITTEE ON MATERIALS FOR ROAD CONSTRUCTION, ETC.

W. W. CROSBY, *Chairman,*
H. K. BISHOP,
A. W. DEAN,
N. P. LEWIS,
C. J. TILDEN,
G. W. TILLSON,
A. H. BLANCHARD, *Secretary.*

APPENDIX A

Forms Originally Prepared and Adopted by the Special Committee, American Society of Civil Engineers, on "Bituminous Materials for Road Construction, and on Standards for Their Test and Use", in 1909.

AMERICAN SOCIETY OF CIVIL ENGINEERS

Special Committee on

Bituminous Materials for Road Construction.

July 31st, 1909.

Dear Sir:

The importance of a better knowledge of the various properties of such Bituminous Materials as are now on the market and of those likely to be used in Road Construction in the near future, and of a clearer understanding of the effects of these properties when such materials have been so used, has doubtless impressed you before this. With a view toward obtaining for the general benefit, conclusions of value at the earliest possible moment, the undersigned have been appointed a Special Committee to investigate and report on Bituminous Materials for Road Construction and on Standards for Their Test and Use.

The Committee has, after due deliberation, concluded that the information called for on the attached form is most desirable for a proper and complete consideration of the matter in hand and in order that clear and definite conclusions may be reached and reported by the Committee. To this end, therefore, the Committee would respectfully request that you furnish on the attached form all the information you find it practicable to express. The Committee realizes fully that the methods of recording information concerning the work in different places may vary considerably and that it may not be possible in all or even many cases to fill in completely the blanks of the form arranged by the Committee. However, the attempt has been made to arrange the form so as to provide for summations where subdivided information shall be impracticable of expression, and the Committee begs to assure you that, even if information in all details cannot be furnished, partial information and figures, such as it shall seem practicable for you to furnish, will be greatly appreciated. It is the opinion of the Committee that the collection of even partial information from various sources may be of great assistance in making clearer many matters now in dispute.

In order for the work of the Committee to be of value to the greatest extent, it is, of course, advisable that it carefully consider in detail

as much information from many sources as it is possible to secure, and the Committee therefore hopes that it may be favored with your co-operation by the furnishing of the information requested. Detailed explanations regarding the filling of the blanks in the form will be found on the last page of the same.

The Committee begs to express here its appreciation of such information and co-operation as you may be able to give it and to subscribe itself,

Very respectfully,

W. W. CROSBY, *Chairman,*
H. K. BISHOP,
A. W. DEAN,
A. H. BLANCHARD, *Secretary,*
Committee.

REMARKS.

.....
.....

NOTES AND EXPLANATIONS.

(1) In stating "nature of subgrade" note whether sandy, clayey, loamy, or otherwise and whether readily and thoroughly compacted by rolling.

(2) "Mean" percentage of grades to be obtained by multiplying length of grade by its per cent., adding all products together and dividing by total length.

(3) If possible "average" should be arrived at from two or three separate determinations. State number of determinations from which "average" is secured.

(4) After "Artificial Foundation, nature," sufficient information should be inserted to indicate whether simply a layer of gravel is used, and nature (sandy or otherwise) of same; or whether a foundation is laid by hand of large stone; or whether a layer of crushed stone is rolled into the subgrade before commencement of surfacing proper.

(5) Under "Equipment" should be stated any charges paid as rentals.

(6) For methods of determination of characteristics listed, see enclosed "List of Analyses and Methods of Testing Bituminous Materials" proposed by Committee.

(7) In reporting "Viscosities" of course figures can only be given in terms of the one (or more) instruments applying in any case.

(8) Give, if possible, geological "name" of material used in each course. Reference, "Rocks," by Kemp.

(9) "Abrasion test" should be stated in terms of French coefficient of wear.

(10) "Fracture" should be stated as "cubical" or "scaly."

(11) "Size" should be stated as maximum and minimum of sizes of openings in screens to pass and hold stone used.

(12) Cross out unit not used.

AMERICAN SOCIETY OF CIVIL ENGINEERS.

Special Committee on Bituminous Materials for Road Construction.

List of Analyses and Methods of Testing Bituminous Materials Proposed by Committee.

July, 1909.

Tars.

Water-Soluble Materials.—Boil gently 2 grams of material with 25 c.c. of distilled water for one hour. Filter and wash with 25 c.c. of boil-

ing water. Evaporate filtrate in weighed dish to dryness and constant weight at 105° C. Weigh residue. Ignite residue and weigh again, giving weight of inorganic matter plus weight of crucible. Weight No. 2 minus weight No. 3 gives weight of organic matter.

Specific Gravity.—Use some standard form of pyknometer. Material and distilled water must have a temperature of 25° C.

For semi-solid and solid materials use Sommer's Pyknometer.

Free Carbon.—The free carbon shall be determined by dissolving for 15 hours, 2 grams of the compound in 100 c.c. of cold carbon bisulphide, filtering the solution through a weighed Gooch crucible, fitted with an asbestos pad, drying to constant weight, and weighing the insoluble residue; then igniting crucible until all carbon is burned off, weighing the residue (ash). The difference between the 2nd and 3rd weights is "Free Carbon." The difference between the 1st and 3rd, is ash, which should be noted.

Fixed Carbon.—About one gram of the compound is weighed into a platinum crucible one and one-eighth to one and one-half inches high. The crucible with the lid on is heated, first gently, and then until no more smoke and flame issues between the crucible and the lid. It is then heated three and one-half minutes in the full heat of the burner; then cooled and weighed. The crucible lid is then removed and the crucible and contents allowed to remain in the full heat of the burner until the carbon is burned off, and then weighed again. The difference between these two weights is the Fixed Carbon.

Evaporation.—20 grams of compound are heated in a flat-bottomed dish, two and one-half inches in diameter and about one inch high, for a total of five hours in three successive periods of three, one and one hours, respectively, in an oven, the interior of which is maintained at a uniform and constant temperature of 170° C. This oven is to be controlled by any thermo regulator, controlling within two degrees, and is to have its full temperature before the compound is introduced. The dish must be level. Remove dish from oven and stir contents thoroughly for one minute between successive periods.

Penetration of Residue from Evaporation Test.—The penetration shall be measured by a standard machine using 100 grams load and No. 2 needle. Use a flat-bottomed glass dish seven-eighths of an inch in diameter and one and one-half inches in height. Fill flush with top with material and allow same to stand at room temperature for one-half hour. Immerse in water bath, covering material for one hour. Immerse needle to be used for five minutes in same bath. Test at once, making three determinations. The recorded penetration will be the average value. Temperature 4° C. and 25° C.

(Note): Residue must be melted at lowest possible temperature and thoroughly mixed by stirring.

Melting Point of Residue from Evaporation.—The material whose melting point is to be determined, is melted and poured into a mold that will make a one-half inch cube. A No. 10 gauge wire about 6″ to 8″ long is bent at right angles for a length of ¾″ at one end and the center of the cube is placed on this end so that one of the diagonals of the vertical face of the cube is parallel to the long part of the wire. Take a bottle of a size about 2″ in diameter and 4″ high and place a piece of white paper in the bottom of it. Pass the long part of the wire through the cork of the bottle so that the lower edge of the cube will be within one inch of the bottom of the bottle. Also put a thermometer through the cork so that the bulb is opposite the cube. Place the bottle in a water or oil bath and raise the temperature of the bath at a rate of three to six degrees C. a minute. The melting point of the material is the temperature of the thermometer inside the bottle at the time that the material touches the paper in the bottom of the bottle.

Distillation.—
Up to 105° C.
From 105° to 170° C.
From 170° to 225° C.
From 225° to 270° C.
From 270° to 300° C.

700 grams of the compound are weighed into a retort (E. & A. four pints, No. 4 521), whose top is fitted with a tee as close as possible to the retort, and a condenser pipe 24″ to 36″ long; the upper branch of the tee is used for the insertion of a thermometer, the top of whose bulb is placed immediately below the main outlet of the tee.

Viscosity or Consistency.—Temperatures at which viscosities will be determined, are 100° C. and 25° C.

Penetrometer to be used in accordance with standard method on materials solid at above temperatures. On materials which at the above temperature, the penetrometer cannot be used, the viscosity shall be determined by one of the following instruments:

Engler Viscosimeter.
Lunge Tar Tester.
New York Testing Laboratory Viscosimeter.

COMPOUNDS PREPARED FROM PETROLEUM OR NATURAL ASPHALT PITCHES.

Melting Point of Solid Asphalts.—Same method as for residue from evaporation of tars.

Water-Soluble Materials.—Same method as for tars.

Specific Gravity.—Same method as for tars.

Free Carbon.—Same method as for tars.

Material Soluble in Cold Carbon-Tetrachloride.—Same method as for Free Carbon, except carbon-tetrachloride is used as a solvent instead of carbon-bisulphide.

Fixed Carbon.—Same method as for tars.

Paraffin.—100 grams or less of the compound is distilled rapidly in a retort to dry coke.

5 grams of the well mixed distillate is treated in a two-ounce flask with 25 c.c. Squibbs absolute ether; after mixing thoroughly, 25 c.c. Squibbs absolute alcohol is added and the flask packed closely in a freezing mixture of finely crushed ice and salt for at least 30 minutes. Filter the precipitate quickly by means of a suction pump, using a No. 575 C. S. & S. 9 c.m. hardened filter paper. Rinse and wash the flask and precipitate (with 1 to 1 Squibbs alcohol and ether mixture cooled to —17° C.) until free from oil (50 c.c. of washing solution is usually sufficient). When sucked dry remove paper, transfer waxy precipitate to small glass dish, evaporate on steam bath and weigh paraffin remaining on dish.

Calculation.—Weight of paraffin divided by weight of distillate taken and multiplied by per cent. of total distillate used from original sample, equals per cent. of paraffin.

Evaporation Test No. 1.—Same method as for tars.

Penetration of Residue from Evaporation Test No. 1.—Same method as for similar residue of tars.

Melting Point of Residue from Evaporation Test No. 1.—Same method as for similar residue of tars.

Solubility in 88° Baumé Naphtha.—2 grams of compound are placed in 4-oz. oil-sample bottle made up to 100 c.c. with 88° B. naphtha, having a boiling point between 40° C. and 55° C., the whole well shaken until compound is broken up. The bottle is then centrifugalized for 10 minutes, 50 c.c. are withdrawn into a weighed flask, the naphtha distilled by a water bath and the residue weighed. Another 10 c.c. of the naphtha solution is run over 3½″ Petri glass and allowed to evaporate for 24 hours at room temperature. Note character of residue, *i. e.*, sticky or oily.

Viscosity or Consistency.—Same as for tars.

Evaporation Test No. 2.—Same method as for tars except oven temperature shall be 205° C.

Penetration of Residue from Evaporation Test No. 2.—Same method as for tars.

Melting Point of Residue from Evaporation Test No. 2.—Same method as for tars.

AMERICAN SOCIETY OF CIVIL ENGINEERS.

SPECIAL COMMITTEE ON
BITUMINOUS MATERIALS FOR ROAD CONSTRUCTION.

To.....
.....
.....

The Committee again acknowledges its indebtedness for co-operation in reporting on the construction of roads, in connection with which bituminous materials were used. The information furnished is of great value, but in order to make it more fully available it seems advisable to request the supplementary information on the points covered by the following form.

The general information previously furnished has been filled in by the Secretary.

It is the intention of the Committee to ask annually for reports, each to cover a year of observation, and it is hoped that this form will be returned as soon as data covering a year are available.

Report on Results of the Use of
BITUMINOUS MATERIALS IN ROAD CONSTRUCTION.

GENERAL INFORMATION.

(Required for identification with previous reports.)

State.....County.....
Town.....Road.....

Motor cycles.....								
" runabouts.....								
" touring cars (four or five seats).....								
" touring cars (six or seven seats) including limousines or landaulets.								
" wagons or drays....								

* If possible, "average" should be arrived at from two or three separate determinations. State number of determinations from which average is secured.

(1) Date of opening road to traffic, or average length of time after completion before sections of road were opened to traffic.
(2) Has the surface begun to disintegrate? If so, when and in what manner? What was the probable cause?
(3) Has any displacement of the surface been manifest in the shape of ruts, waves, etc.?
(4) Was the surface objectionably soft in hot weather? If so, state air temperature; also state maximum temperature at which surface was satisfactory.
(5) Is the tractive effort increased by the presence of the bituminous material?
(6) Was the surface slippery for horses or motor cars in (1) cold weather, (2) when wet, (3) on frosty mornings?
(7) Are the stones of the top course of the macadam visible? If so, to what extent?
(8) Has the surface worn differently adjacent to curbs and car rails than it has in the traveled ways?
(9) During what period covered by this report was the surface coated with snow or ice?
(10) Maximum depth of frost in this period.
(11) Amount of rainfall for the period covered by this report.
(12) Has the surface been artificially watered? If so, to what extent?
(13) Has surface been cleaned? If so, to what extent?
(14) Is road shaded or exposed?
(15) Cost and character of maintenance during period covered by this report.
(16) Your general opinion on the results secured on the above road and any information not covered properly by the above is desired.
(Then follows a space for answers to the foregoing questions and for date and name, title, and address of the reporting officer.)

APPENDIX B

Revised Forms Prepared and Adopted by the Special Committee, American Society of Civil Engineers, on "Materials for Road Construction, and on Standards for Their Test and Use", in 1914.

Bituminous Materials for Road Construction and Standards for Their Test and Use.

Special Committee of the American Society of Civil Engineers.

Dear Sir:

Without doubt you fully appreciate the value of a comprehensive record of the details of construction and maintenance of bituminous surfaces and bituminous pavements and of the effects of the various chemical and physical properties of bituminous materials when used in connection with different non-bituminous materials under diverse methods of construction and maintenance of roads and pavements. With a view toward obtaining for the general benefit conclusions of value, the Board of Direction of the Society appointed a Special Committee to investigate and report on "Bituminous Materials for Road Construction and on Standards for Their Test and Use."

This Committee, in continuation of its work of collating information, has issued a second form for use in recording data relative to the construction of bituminous surfaces and bituminous pavements. The Committee has concluded that the information called for on the enclosed form is desirable for a proper consideration of the matter in hand and in order that clear and definite conclusions may be reached. To this end, therefore, the Committee would respectfully request that you furnish on the forms information relative to the bituminous surfaces and bituminous pavements built during the preceding and current construction seasons, using one form for each surface or pavement. The Committee assures you that, even if information on all the details cannot be furnished, partial facts and figures, such as it shall seem practicable for you to furnish, will be greatly appreciated.

In order that the work of the Committee may be of value to the greatest extent, it is advisable that it carefully consider in detail as much information from as many sources as it is possible to secure, and the Committee therefore hopes that it may be favored with your co-operation by the receipt from you of the information solicited.

Thanking you for a consideration of the above request, we remain,

Very respectfully,

By order of the Committee,

August, 1914. A. H. Blanchard, *Secretary.*

Bituminous Materials for Road Construction and Standards for Their Test and Use.

APPENDIX C

ANALYSES AND TESTS OF BITUMINOUS MATERIALS.

The adoption of the following lists of tests, as including all those probably of value in determining and recording the characteristics of the bituminous materials used in this connection, is recommended:

TARS.

Specific gravity at 25° cent. (77° Fahr.).
Flash point.
Solubility in CS_2 (carbon disulphide).
Consistency at 4° cent. (39° Fahr.), 25° cent. (77° Fahr.), 46° cent. (115° Fahr.), 98° cent. (208° Fahr.).
Melting point.
Loss on evaporation at 163° cent. (325° Fahr.).
    Consistency of residue at 4° cent. (39° Fahr.), 25° cent. (77° Fahr.), 46° cent. (115° Fahr.), 98° cent. (208° Fahr.).
    Melting point of residue.
Distillation.
    Consistency of residue at 4° cent. (39° Fahr.), 25° cent. (77° Fahr.), 46° cent. (115° Fahr.), 98° cent. (208° Fahr.).
    Melting point of residue.

ASPHALTIC MATERIALS.

Specific gravity at 25° cent. (77° Fahr.).
Flash point.
Solubility in CS_2 (carbon disulphide).
Solubility of bitumen in CCl_4 (carbon tetrachloride).
Solubility of bitumen in petroleum naphtha.
    Character of residue on glass.
Consistency at 4° cent. (39° Fahr.), 25° cent. (77° Fahr.), 46° cent. (115° Fahr.), 98° cent. (208° Fahr.).
Melting point.
Ductility at 4° cent. (39° Fahr.) and 25° cent. (77° Fahr.).
Fixed carbon content.
Paraffin content.
Loss on evaporation at 163° cent. (325° Fahr.).
    Consistency of residue at 4° cent. (39° Fahr.), 25° cent. (77° Fahr.), 46° cent. (115° Fahr.).
    Melting point of residue.
    Ductility of residue at 4° cent. (39° Fahr.) and 25° cent. (77° Fahr.).

It is further recommended that the following methods for performing the tests above listed be adopted as standard:

Specific Gravity.

For liquid and semi-solid materials, some standard form of pyknometer shall be used. For solid materials, the suspension method shall be used. Material and distilled water shall have a temperature of 25° cent. (77° Fahr.).

The pyknometer to be used shall consist of a fairly heavy, straight-walled glass tube, 70 mm. (2.75 in.) long and 22 mm. (0.875 in.) in diameter, ground to receive a solid glass stopper with a hole of 1.6-mm. (0.063-in.) bore, in place of the usual capillary opening. The lower part of this stopper shall be made concave in order to allow all air bubbles to escape through the bore. The depth of the cup-shaped depression is 4.8 mm. (0.188 in.) at the center. The stoppered tube shall have a capacity of about 24 cu. cm. (0.811 oz.) and when empty shall weigh about 28 grammes. Its principal advantages are: (1) that any desired quantity of bituminous material may be poured in without touching the sides above the level desired; (2) it is easily cleaned; (3) on account of the 1.6-mm. (0.063-in.) bore, the stopper can be more easily inserted when the tube is filled with a very viscous oil than if it contained a capillary opening. When testing solid or semi-solid materials with the pyknometer, extreme care should be taken in melting, to avoid loss by evaporation, and, in filling the pyknometer, to avoid entrapping air.

When working with semi-solid bituminous materials which are too soft to be broken and handled in fragments, the following method of determining their specific gravity has been used with good results. The clean, dry pyknometer is first weighed empty and this weight is called *a*. It is then filled in the usual manner with freshly distilled water at 25° cent. (77° Fahr.), and the weight is again taken and called *b*. A small quantity of the material is then placed in a spoon and brought to a fluid condition by the gentle application of heat, with care that no loss by evaporation occurs. When sufficiently fluid, enough is poured into the dry pyknometer, which may also be warmed, to fill it about half full, without allowing the material to touch the sides of the tube above the desired level. The tube and contents are then allowed to cool to room temperature, after which the tube is carefully weighed with the stopper. This weight is called *c*. Distilled water, at 25° cent. (77° Fahr.), is then poured in until the pyknometer is full. After this the stopper is inserted and the whole is cooled to 25° cent. (77° Fahr.) by a 30-min. immersion in a beaker of distilled water maintained at this temperature. All surplus moisture is then removed with a soft cloth, and the pyknometer and contents are weighed. This weight is called *d*. From the weights

obtained, the specific gravity of the material may be readily calculated by the following formula:

$$\left.\begin{matrix}\text{Specific gravity } 25^\circ \text{ cent. } (77^\circ \text{ Fahr.})\\ 25^\circ \text{ cent. } (77^\circ \text{ Fahr.})\end{matrix}\right\} = \frac{c - a}{(b - a) - (d - c)}.$$

Both a and b are constants, and need be determined only once. It is necessary, therefore, to make only two weighings for each determination after the first. Results obtained according to this method are accurate to within two units in the third decimal place, whereas the open-tube method commonly used is accurate to the second decimal place only.

The specific gravity of fluid bituminous material may be determined in the ordinary manner with this pyknometer by completely filling it with the material and dividing the weight of the bituminous material thus obtained by that of the same volume of water.

Flash Point.

The flash point shall be determined by the closed-cup test.

Although for ordinary purposes, the open-cup method of determining the flash and burning points of bituminous materials is reasonably accurate, the closed-cup method described below is to be preferred.

The oil tester shall consist of a copper oil cup having a capacity of about 300 cu. cm. (10.1 oz.), and shall be heated in a water or oil bath by a small Bunsen flame. The cup shall be provided with a glass cover, carrying a thermometer, and a hole for inserting the testing flame. The testing flame shall be obtained from a jet of gas passed through the piece of glass tubing, and shall be about 5 mm. (0.197 in.) in length.

The flash test shall be made as follows: The oil cup shall first be removed and the bath filled with water or cottonseed oil. The oil may always be used, and is necessary for bituminous material flashing at a temperature of more than 100° cent. (212° Fahr.). The oil cup shall be replaced and filled with the material to be tested to within 3 mm. (0.118 in.) of the flange joining the cup and the vapor chamber above. The glass cover shall then be placed on the oil cup and the thermometer adjusted so that its bulk shall be just covered by the bituminous material. The Bunsen flame shall be applied in such a manner that the temperature of the material in the cup shall be raised at the rate of about 5° cent. (9° Fahr.) per min. From time to time the testing flame shall be inserted in the opening in the cover to about half way between the surface of the material and the cover. The appearance of a faint bluish flame over the entire surface of the bituminous material will show that the flash point has been reached and the temperature at this point is taken.

Solubility in Carbon Disulphide (CS_2).

This test shall consist in dissolving the bituminous material in carbon disulphide and recovering any insoluble matter by filtering the solution through an asbestos felt. The Gooch crucible used for the determination shall be 4.4 cm. (1.722 in.) wide at the top, tapering to 3.6 cm. (1.417 in.) at the bottom, and shall be 2.5 cm. (0.984 in.) deep.

The asbestos shall be cut with scissors into pieces not exceeding 1 cm. (0.394 in.) in length, after which it shall be shaken up with just sufficient water to pour easily. The crucible shall be filled with the suspended asbestos and allowed to settle for a few moments. A light suction shall then be applied to draw off all the water and leave a firm mat of asbestos in the crucible. More of the suspended material shall be added, and the operation shall be repeated until the felt shall be so dense that it scarcely transmits light when held so that the bottom of the crucible is between the eye and the source of light. The felt shall then be washed several times with water, and drawn firmly against the bottom of the crucible by an increased suction. The crucible shall be removed to a drying oven for a few minutes, after which it shall be ignited at red heat over a Bunsen burner, cooled in a desiccator and weighed.

Two grammes of bituminous material or 10 grammes of an asphalt topping or rock asphalt shall then be placed in an Erlenmeyer flask, which shall have been weighed previously, and the accurate weight of the sample obtained. One hundred cubic centimeters (3.381 oz.) of chemically pure carbon disulphide shall be poured into the flask, in small portions, with continual agitation, until all lumps disappear and nothing adheres to the bottom. The flask shall then be corked and set aside for 15 min. to allow settlement of the insoluble material.

The weighed Gooch crucible containing the felt shall be set up over the dry pressure flask, and the solution of bituminous material in carbon disulphide shall be decanted through the felt without suction by gradually tilting the flask, with care not to stir up any precipitate that may have settled out. At the first sign of any sediment coming out, the decantation shall be stopped and the filter allowed to drain. A small quantity of carbon disulphide shall then be washed down the sides of the flask, after which the precipitate shall be brought upon the felt and the flask scrubbed, if necessary, with a feather or "policeman", to remove all adhering material. The contents of the crucible shall be washed with carbon disulphide until the washings run colorless. Suction shall then be applied until there is practically no odor of carbon disulphide in the crucible, after which the outside of the crucible shall be cleaned with a small quantity of the solvent. The crucible and contents shall be dried in the hot-air oven at 100° cent. (212° Fahr.) for about 20 min., cooled in a

desiccator, and weighed. If any appreciable quantity of insoluble matter adheres to the flask, it shall also be dried and weighed, and any increase over the original weight of the flask shall be added to the weight of insoluble matter in the crucible. The total weight of insoluble material may include both organic and mineral matter. The former, if present, shall be burned off by ignition at a red heat until no incandescent particles remain, thus leaving the mineral matter or ash, which can be weighed on cooling. The difference between the total weight of material insoluble in carbon disulphide and the weight of substance taken equals the total bitumen, and the percentage weights are calculated and reported as total bitumen, and insoluble organic and inorganic matter, on the basis of the weight of material taken for analysis.

This method is quite satisfactory for straight oil and tar products, but, where native asphalts are present, it will be found practically impossible to retain all the finely divided mineral matter on an asbestos felt. It is generally more accurate, therefore, to obtain the result for total mineral matter by direct ignition of a 1-gramme sample in a platinum crucible, or to use the result for ash obtained in the fixed carbon test. The total bitumen is then determined by deducting from 100% the sum of the percentages of total mineral matter and insoluble organic matter. If the presence of a carbonate mineral is suspected, the percentage of mineral matter may be most accurately obtained by treating the ash from the fixed carbon determination with a few drops of ammonium carbonate solution, drying at 100° cent. (212° Fahr.), then heating for a few minutes at a dull red heat, cooling, and weighing again.

When difficulty in filtering is experienced—for instance, when Trinidad asphalt is present in any quantity—a longer period of subsidence than 15 min. is necessary, and the following method, proposed by the Committee on Standard Tests for Road Materials (Committee D-4) of the American Society for Testing Materials, is recommended: (Note: English equivalents in brackets have been added by the Special Committee on Materials for Road Construction).

From 2 to 15 grammes (depending on the richness in bitumen of the substance) is weighed into a 150-cu. cm. (5.072-oz.) Erlenmeyer flask, the tare of which has been previously ascertained, and treated with 100 cu. cm. (3.381 oz.) of carbon disulphide. The flask is then loosely corked and shaken from time to time until practically all large particles of the material have been broken up, when it is set aside and not disturbed for 48 hours. The solution is then decanted off into a similar flask that has been previously weighed, as much of the solvent being poured off as possible without disturbing the residue. The first flask is again treated with fresh carbon disulphide and shaken as before, when it is put away with the second flask and not disturbed for 48 hours.

At the end of this time the contents of the two flasks are carefully decanted off upon a weighed Gooch crucible fitted with an asbestos filter, the contents of the second flask being passed through the filter first. The asbestos filter shall be made of ignited long-fiber amphibole, packed in the bottom of a Gooch crucible to the depth of not more than $\frac{1}{8}$ in. After passing the contents of both flasks through the filter, the two residues are shaken with more fresh carbon disulphide and set aside for 24 hours without disturbing, or until it is seen that a good subsidation has taken place, when the solvent is again decanted off upon the filter. This washing is continued until the filtrate or washings are practically colorless.

The crucible and both flasks are then dried at 125° cent. (257° Fahr.) and weighed. The filtrate containing the bitumen is evaporated, the bituminous residue burned, and the weight of the ash thus obtained added to that of the residue in the two flasks and the crucible. The sum of these weights deducted from the weight of substance taken gives the weight of bitumen extracted.

Solubility of Bitumen in Carbon Tetrachloride (CCl_4).

The test shall be conducted in exactly the same manner as described for the test for "Solubility in Carbon Disulphide", except that 100 cu. cm. (3.381 oz.) of chemically pure carbon tetrachloride shall be used in place of carbon disulphide, and the percentage of bitumen insoluble in carbon tetrachloride shall be reported on the basis of the bitumen taken as 100, the quantity of bitumen having been determined by the method described under the heading "Solubility in Carbon Disulphide."

Consistency.

The "Engler Viscosimeter," the "New York Testing Laboratory Float," or the "Penetrometer," shall be used, as practicable, at 4° cent. (39° Fahr.), 25° cent. (77° Fahr.), 46° cent. (115° Fahr.), and 98° cent. (208° Fahr.).

Viscosity Test.

The viscosity of liquid bituminous materials shall be determined at any desired temperature by using the "Engler Viscosimeter." This apparatus consists of a brass vessel for holding the material to be tested, and is closed by a cover. To the conical bottom is fitted a conical outflow tube exactly 20 mm. (0.787 in.) long, with a diameter of 2.9 mm. (0.114 in.) on top, and of 2.8 mm. (0.110 in.) on the bottom. This tube is closed and opened by a pointed hardwood stopper. Pointed metal projections are placed on the inside of the vessel at equal distances from the bottom, and serve for measuring the charge of material, which is 240 cu. cm. (8.116 oz.). A thermometer is used to ascertain the temperature of the material to be tested. The vessel is surrounded by a brass jacket, which holds the material which may be used as a heating bath, either water or

cottonseed oil, according to the temperature at which the test is to be made. A tripod serves as a support for the apparatus, and also carries a ring burner by which the bath is heated directly. The measuring cylinder, having a capacity of 100 cu. cm. (3.381 oz.), which is sufficiently accurate for work with road materials, is placed directly under the outflow tube.

As all viscosity determinations should be compared with that of water at 25° cent. (77° Fahr.), the apparatus shall have been previously calibrated as follows: The cup and outlet tube shall first be scrupulously cleaned. A piece of soft tissue paper is convenient for cleaning the tube. The stopper shall then be inserted in the tube, and the cup shall be filled with water at 25° cent. (77° Fahr.) to the top of the projections. The measuring cylinder shall be placed directly under the outflow tube so that the material, on flowing out, will not touch the sides. The stopper shall then be removed and the time required, both for 50 and 100 cu. cm. (1.691 and 3.381 oz.) to run out, shall be ascertained by using a stop-watch. The results thus obtained shall be checked a number of times. The time required for 50 cu. cm. (1.691 oz.) of water should be about 11 sec. and for 100 cu. cm. (3.381 oz.) about 22.8 sec.

Bituminous materials shall be tested in the same manner as water, and the temperature at which the test is made shall be controlled by the bath. The material shall be brought to the desired temperature and maintained there for at least 3 min. before making the test. The results are expressed as specific viscosity compared with water at 25° cent. (77° Fahr.), as follows:

$$\text{Specific viscosity at —— degrees centigrade for —— cu. cm.} = \frac{\text{seconds for passage of given volume at —— degrees centigrade}}{\text{seconds for passage of same volume of water at 25° cent. (77° Fahr.)}}.$$

Float Test.

The float apparatus consists of two parts, an aluminum float or saucer and a conical brass collar. The two parts are made separately, so that one float may be used with a number of brass collars.

In making the test, the brass collar shall be placed with the small end down on the brass plate, which shall have been previously amalgamated with mercury by rubbing it first with a dilute solution of mercuric chloride or nitrate and then with mercury. A small quantity of the material to be tested shall be heated in the metal spoon until quite fluid, with care that it shall suffer no appreciable loss by volatilization and that it shall be kept free from air bubbles. It shall then be poured into the collar in a thin stream until slightly more than level with the top. After the material has cooled to room temperature, the surplus may be removed with a spatula blade which

has been slightly heated. The collar and plate shall then be placed in one of the tin cups containing ice water maintained at 5° cent. (41° Fahr.), and left in this bath for 15 min. Meanwhile, the other cup shall be filled about three-fourths full of water and placed on the tripod, and the water shall be heated to any temperature desired for the test. This temperature shall be accurately maintained, and shall at no time throughout the entire test be allowed to vary more than 0.5° cent. (0.9° Fahr.) from the temperature selected. After the material to be tested has been kept in the ice water for 15 min., the collar and contents shall be removed from the plate and screwed into the aluminum float, which shall then be immediately floated in the warmed bath. As the plug of bituminous material becomes warm and fluid, it is gradually forced upward and out of the collar, until water gains entrance to the saucer and causes it to sink.

The time, in seconds, between placing the apparatus on the water and when the float sinks shall be taken as a measure of the consistency of the material under examination.

Penetration Test.

The penetration test for determining the consistency of a material shall be made by measuring the distance a weighted needle will penetrate into the material at a given temperature. A standard No. 2 cambric needle, weighted with 100 grammes, shall be used, except as noted below, and the depth of penetration shall be determined on the bituminous material maintained at 25° cent. (77° Fahr.) while the load is applied for 5 sec. When the penetration test, made as above described, will give a result of less than 10 or more than 350, the loading and time shall be changed to 200 grammes for 1 min., and 50 grammes for 5 sec., respectively. The penetration test shall also be made on the bituminous material under the following conditions whenever practicable: Penetration at 4° cent. (39° Fahr.) with a weight of 200 grammes for 1 min.; penetration at 46° cent. (115° Fahr.) with a weight of 50 grammes for 5 sec. The loading. time, and temperature shall be reported, with the resulting penetration in every case. The unit of penetration shall be reported as 0.1 mm.

The penetration test is made as follows:

The sample of the material to be tested shall first be warmed just sufficiently to flow freely, stirred thoroughly, and poured into a flat-bottomed tin box, 5.715 cm. (2.25 in.) in diameter, and with sides about 3.810 cm. (1.5 in.) in height. The box and contents, after cooling in the air in the laboratory for 10 min., shall be immersed in ice water for 20 min., and shall then be placed in water maintained at the temperature at which the material is to be tested, and allowed to remain immersed for 2 hours, during which period the water containing the sample shall be maintained at the prescribed temperature

accurately and constantly. The sample, in a glass cup and covered with as much water, at the temperature at which the material is to be tested, as may be convenient without spilling, shall now be removed to the penetrometer. The needle shall have been firmly fixed in the machine and shall now be lowered with its holder until the point of the needle almost touches the surface of the sample. It shall then be cautiously brought down until the point of the needle just comes in contact with the surface of the sample; as will best be seen by having a light placed in such a way that, on looking through the sides of the glass cup, the needle will be reflected from the surface of the sample. After thus setting the needle, the rod connected with the recording dial shall be slowly lowered until the foot of the rod shall rest on the head of that part of the penetrometer carrying the needle, and a reading of the dial shall be taken, or the dial shall be adjusted to read at a convenient figure, such as 0 or 100.

Simultaneously noting the time and releasing the needle plunger, which shall have been previously weighted properly for the particular conditions above mentioned, the needle shall be allowed to act freely for exactly 5 sec., as determined by a pendulum or by a chronometer, when it shall be stopped. The rod shall then be lowered until it rests on the head of the part of the instrument carrying the needle, and the difference between the first and second readings of the dial shall be taken as the distance penetrated by the needle, or the penetration.

Owing to the susceptibility of certain bituminous materials to slight changes in temperature, the water bath must be maintained accurately at the desired temperature both before and during the test, and, if the room temperature differs greatly from that of the bath, the water in the glass cup shall be renewed from the bath after each trial. An average of from three to five trials, which should not differ from one another more than three units, shall be taken as the penetration of the sample.

The needle shall be cleaned thoroughly by wiping with a dry cloth before and after each trial. The point of the needle should be examined with a magnifying glass from time to time to see if it has become injured in any way. If it is found to be defective, the needle shall be replaced with a perfect one. Care shall be taken that the needle, in place in the machine and released for action, shall be loaded as required.

Melting Point.

The material under examination shall be first melted in a spoon by the gentle application of heat until sufficiently fluid to pour readily. Care shall be taken that it suffers no appreciable loss by volatilization. It shall then be poured into a 12.7-mm. (0.5-in.) brass cubical mould, which shall have been amalgamated with mercury and shall be placed

on an amalgamated brass plate. The brass may be amalgamated by washing it first with a dilute solution of mercuric chloride or nitrate, after which the mercury is rubbed into the surface. By this means the bituminous material is, to a considerable extent, prevented from sticking to the sides of the mould. The hot material shall slightly more than fill the mould, and, when cooled, the excess shall be cut off with a hot spatula.

After cooling to room temperature, the cube shall be removed from the mould and fastened on the lower arm of a No. 10 wire (B. & S. gauge), bent at right angles at one end and suspended beside a thermometer in a covered Jena glass beaker having a capacity of 400 cu. cm. (13.526 oz.), which shall be placed in a water bath, or, for high temperatures, a cottonseed-oil bath. The wire shall be passed through the center of two opposite faces of the cube, which shall then be suspended with its base 25.4 mm. (1 in.) above the bottom of the beaker. The water or oil bath shall consist of an 800-cu. cm. (27.051-oz.) low-form Jena glass beaker suitably mounted for the application of heat from below. The beaker in which the cube is suspended shall be of the tall-form Jena type, without lip. The metal cover shall have two openings. A cork, through which passes the long arm of the wire, shall be inserted in one hole and the thermometer in the other. The bulb of the thermometer shall be just level with the cube and at an equal distance from the side of the beaker. In order that a reading of the thermometer may be made, if necessary, at the point which passes through the cover, the hole shall be triangular and covered with an ordinary object glass through which the stem of the thermometer may be seen. Readings made through this glass shall be calibrated to the angle of observation, which may be made constant by sighting always from the front edge of the opening to any given point on the stem of the thermometer below the cover.

After the test specimen shall have been placed in the apparatus, the liquid in the outer vessel shall be heated in such a manner that the thermometer registers an increase of 5° cent. (9° Fahr.) per min. The temperature at which the bituminous material touches a piece of paper placed in the bottom of the beaker shall be taken as the melting point. Determinations made in the manner described shall not vary more than 2° cent. (3.6° Fahr.) for successive trials on the same material. At the beginning of this test the temperature of both bituminous material and bath shall be approximately at 25° cent. (77° Fahr.).

Loss on Evaporation.

Fifty grammes of the material shall be heated in a flat bottomed dish, 5.715 cm. (2.25 in.) in diameter and with sides about 3.810 cm. (1.5 in.) high for a total of 5 hours in three successive periods of 3, 1, and 1 hours, respectively, in a well-ventilated oven, the interior of

which shall be maintained at a uniform and constant temperature of 163° cent. (325° Fahr.). The oven temperature shall be controlled by any thermo-regulator effective within 2° cent. (3.6° Fahr.), and shall be brought to its full temperature before the material is introduced. The dish shall be level, and its contents, without removal from the oven, shall be stirred thoroughly for 1 min. between the successive periods mentioned. In preparing the residue for the penetration test, it shall first be heated, and thoroughly stirred while cooling.

Distillation.

(Method recommended by the Sub-Committee on Distillation of the American Society for Testing Materials. Note: Equivalents in English units, have been added by the Special Committee on Materials for Road Construction.)

Sampling.—The sample as received shall be thoroughly stirred and agitated, warming, if necessary, to insure a complete mixture before the portion for analysis is removed.

Dehydration.—If the presence of water is suspected, or known, the material shall be dehydrated before distillation. About 500 cu. cm. (16.907 oz.) of the material is placed in an 800-cu. cm. (27.051-oz.) copper still provided with a distilling head connected with a water-cooled condenser. A ring burner is used, starting with a small flame at the top of the still, and gradually lowering it, if necessary, until all the water has been driven off. The distillate is collected in a 200-cu. cm. separatory funnel with the tube cut off close to the stop-cock. When all the water has been driven over and the distillate has settled out, the water is drawn off and the oils are returned to the residue in the still. The contents of the still shall have cooled to below 100° cent. (212° Fahr.) before the oils are returned, and they shall be well stirred and mixed with the residue.

Apparatus.—The apparatus shall consist of the following standard parts:

(*a*) Flask.—The distillation flask shall be a 250-cu. cm. Engler distilling flask, having the following dimensions:

Diameter of bulb	8.0 cm.	(3.150 in.)
Length of neck	15.0 "	(5.906 ")
Diameter of neck	1.7 "	(0.670 ")
Surface of material to lower side of tubulature	11.0 "	(4.331 ")
Length of tubulature	15.0 "	(5.906 ")
Diameter of tubulature	0.9 "	(0.354 ")
Angle of tubulature	75°	

A variation of 3% from the foregoing measurements will be allowed.

(*b*) Thermometer.—The thermometer shall be of hardened glass, filled with carbon dioxide under pressure, and provided with an

expansion chamber at the top; it shall read to 450° cent. (842° Fahr.), shall be graduated in single degrees, centigrade, and shall have the following dimensions:

Diameter of stem....	6.75	to	7.25	mm.	(0.266	to	0.286	in.)
Length of thermometer	335	"	350	"	(13.189	"	13.780	")
Length from 0° to 450° marks	285	"	300	"	(11.221	"	11.811	")
Length of bulb.....	20	"	22	"	(0.787	"	0.866	")
Diameter of bulb....	5.25	"	6.50	"	(0.207	"	0.256	")

It shall rise from 15° to 95° cent. (59° to 203° Fahr.) in not less than 3 sec. nor more than 5 sec. when plunged into boiling water.

The thermometer shall be set up as for the distillation test, using water, napthalene, and dimethylamine as distilling liquids. The correctness of the thermometer shall be checked at 0° cent. (32° Fahr.) and 100° cent. (212° Fahr.) after each third distillation until seasoned.

(*c*) Condenser.—The condenser tube shall have the following dimensions:

Length			500	mm.	(19.685	in.)		
Width	12	to	15	"	(0.472	to	0.591	in.)
Width of adaptor end.....	20	"	25	"	(0.787	"	0.984	")

(*d*) Stands.—Two iron stands shall be provided, one with a universal clamp for holding the condenser, and one with a light grip arm with a cork-lined clamp for holding the flask.

(*e*) Burner and Shield.—A Bunsen burner shall be provided, with a tin shield, 20 cm. (7.784 in.) long and 9 cm. (3.543 in.) in diameter. The shield shall have a small hole through which to observe the flame.

(*f*) Cylinders.—The cylinders used in collecting the distillate shall have a capacity of 25 cu. cm. (0.845 oz.), and shall be graduated in tenths of a cubic centimeter.

Setting up the Apparatus.—The apparatus shall be set up, the thermometers being placed so that the top of the bulb is opposite the middle of the tubulature. All connections shall be tight.

Method.—One hundred cubic centimeters (3.381 oz.) of the dehydrated material to be tested shall be placed in a tared flask and weighed. After adjusting the thermometer, shield, condenser, etc., the distillation is commenced, the rate being regulated so that 1 cu. cm. (0.034 oz.) passes over every minute. The receiver is changed as the mercury column just passes the fractionating point.

			Up to 110°		cent.	(230°	Fahr.)	
110°	cent.	"	170°	"		(338°	"	)
170°	"	"	235°	"		(455°	"	)
235°	"	"	270°	"		(518°	"	)
270°	"	"	300°	"		(572°	"	)

To determine the quantity of residue, the flask is weighed again when distillation is complete. During the distillation the condenser tube shall be warmed when necessary, in order to prevent the deposition of any sublimate. The percentages of fraction should be reported, both by weight and by volume.

Ductility.

A briquette of the material to be tested shall be formed by pouring the molten material into a briquette mould. The dimensions of the briquette shall be: 1 cm. (0.394 in.) in thickness throughout its entire length; distance between the clips or end pieces, 3 cm. (1.181 in.); width of asphalt cement section at mouth of clips, 2 cm. (0.787 in.); width at minimum cross-section, half way between clips, 1 cm. (0.394 in.). The center pieces are removable, the briquette mould being held together during moulding with a clamp or wire.

The moulding of the briquette shall be done as follows: The two center sections shall be well amalgamated to prevent the asphalt cement from adhering to them, and the briquette mould shall then be placed on a freshly amalgamated brass plate. The asphalt cement to be tested, while in a molten state, shall be poured into the mould, a slight excess being added to allow for shrinkage on cooling. When the asphalt cement in the mould is nearly cool, the briquette shall be cut off level, with a warm knife or spatula. When it is thoroughly cooled to the temperature at which it is desired to make the test, the clamp and the two side pieces are removed, leaving the briquette of asphalt cement held at each end by the ends of the mould, which now play the part of clips. The briquette shall be kept in water for 30 min. at 4° cent. (39° Fahr.) or 25° cent. (77° Fahr.) before testing, dependent on the temperature at which the ductility is desired. The briquette with the clips attached shall then be placed in a "ductility test machine" filled with water at one of the above temperatures to a sufficient height to cover the briquette not less than 50 mm. (1.969 in.). This machine consists of a rectangular water-tight box, having a movable block working on a worm-gear from left to right. The left clip is held rigid by placing its ring over a short metal peg provided for this purpose; the right clip is placed over a similar rigid peg on the movable block. The movable block is provided with a pointer which moves along a centimeter scale. Before starting the test, the centimeter scale is adjusted to the pointer at zero. Power is then applied by the worm-gear pulling from left to right at the uniform rate of 5 cm. (1.969 in.) per min. The distance, in centimeters, registered by the pointer on the scale at the time of rupture of the thread of asphalt cement shall be taken as the ductility of the asphalt cement.

Solubility in Petroleum Naphtha, and Character of Residue on Glass.

Two grammes of the material shall be placed in a 4-oz. oil-sample bottle, made up to 100 cu. cm. (3.381 oz.) with 88° Baumé petroleum naphtha (boiling point between 40° cent. (104° Fahr.) and 55° cent. (131° Fahr.), and the whole well shaken until the sample is digested. The bottle shall then be centrifugalized for 10 min., 50 cu. cm. (1.691 oz.) withdrawn into a weighed flask, the naphtha distilled off by a water bath, and the residue weighed. From this weight the percentage of solubility shall be calculated.

Although there is no generally accepted method of determining the stickiness or oiliness of bituminous materials, except by the unsatisfactory method of handling, a test which has been used to a limited extent, and is based on the character of the residue on glass, appears to the Committee to give promise. This test is made as follows:

One-half gramme of the residue obtained as just specified shall then be placed in the center of a circular glass disk, 32.258 sq. cm. (5 sq. in.) in area, and a similar disk shall be imposed upon it. By warming and pressure of the fingers the material shall be as evenly distributed as practicable over the adjacent surfaces of the disks, and the disks with the material between them shall then be stored under a weight of 1 kg. and at a temperature of 25° cent. (77° Fahr.) for at least 2 hours. The disks shall then be pulled apart horizontally and in a direction truly parallel to their facial diameters at a regular rate of movement of 2.540 cm. (1 in.) per min., the maximum stress, in grammes, required being recorded and reported.

Fixed Carbon.

One gramme of the bituminous material shall be placed in a platinum crucible weighing between 20 and 30 grammes, between 28 and 38 mm. (1.102 and 1.496 in.) in height, and having a tightly fitting cover provided with a flange about 4 mm. (0.157 in.) in depth. The crucible and its contents shall then be heated, first gently and then more severely, until no smoke or flame shall issue between the crucible and the lid. It shall then be placed in the full flame of a Bunsen burner for 7 min., holding the cover down with the end of a pair of tongs until the most volatile products shall have been burned off. The crucible shall be supported on a platinum triangle with the bottom 6 to 8 cm. (2.362 to 3.150 in.) above the top of the burner. The flame shall be fully 20 cm. (7.874 in.) high when burning free, and the determination shall be made in a place free from drafts. The upper surface of the cover shall burn clear, but the under surface may or may not be covered with carbon, dependent on the character of the bituminous material. The crucible shall be removed to the desicca-

tor, and, when cool, shall be weighed, after which the cover shall be removed and the crucible placed in an inclined position over the Bunsen burner and ignited until nothing but ash remains. Any carbon deposited on the cover shall also be burned off. The weight of ash remaining shall be deducted from the weight of the residue after the first ignition of the sample. The resulting weight is that of the fixed carbon, which shall be calculated on the basis of the total weight of the sample, exclusive of mineral matter.

Paraffin.

One hundred grammes of the material shall be distilled rapidly in a retort to a dry coke. Five grammes of the distillate shall then be thoroughly mixed in a 60-cu. cm. (2.029-oz.) flask with 25 cu. cm. (0.845 oz.) of Squibbs' absolute ether. Twenty-five cu. cm. (0.845 oz.) of Squibbs' absolute alcohol shall then be added, and the flask packed closely in a freezing mixture of finely crushed ice and salt for at least 30 min. The precipitate shall be filtered out quickly with a suction pump, using a No. 575 C. S. and S. 9-cm. hardened filter paper. The flask and precipitate shall then be rinsed and washed with a mixture of equal parts of Squibbs' alcohol and ether cooled to — 17° cent. (1° Fahr.) until free from oil (50 cu. cm. (1.691 oz.) of washing solution is usually sufficient). When sucked dry, the filter paper shall be removed and the waxy precipitate transferred to a small glass disk and evaporated on a steam bath. The residue (paraffin) remaining on the disk shall be weighed, and from this weight the percentage on the original 5-gramme sample shall be calculated.

(Note: Although the foregoing method is the one in general use, the following modification is believed by the Committee to promise accurate results and to merit thorough trial.)

One hundred grammes of the material shall be distilled rapidly in a retort to dry coke. The distillate shall then be thoroughly mixed. A 5-gramme sample of the distillate shall be placed in a tared 60-cu. cm. (2.029-oz.) flask with 25 cu. cm. (0.845 oz.) of Squibbs' ether. Twenty-five cubic centimeters (0.845 oz.) of Squibbs' alcohol shall be added, after which the mixture shall be shaken well and the flask packed closely in a freezing mixture of finely crushed ice and salt for at least 30 min. Without removing the flask from the freezing mixture, the solvent shall be sucked from the precipitated paraffin by using a tube connected with the filter pump, the end of the tube being covered with an accurately weighed tuft of absorbent cotton. When the solvent is all removed, the flask shall be taken from the freezing mixture and the cotton tuft pushed off the tube into the flask. The waxy precipitate shall be dissolved, with the tuft of cotton, in 25 cu. cm. (0.845 oz.) of Squibbs' absolute ether. Twenty-five cubic centimeters (0.845 oz.) of

Squibbs' absolute alcohol shall then be added and the flask placed in the freezing mixture again for 30 min. The solvent shall then be removed with the pump and tube as described previously, keeping the flask in the freezing mixture. The second cotton tuft shall be pushed into the flask. The flask and contents shall then be placed in the drying oven at 100° cent. (212° Fahr.) until constant weight shall be reached. This weight, less the weight of the cotton used and less the weight of the tared flask, is the weight of the paraffin. Calculate the weight of the paraffin to a percentage of the original material.

PROGRESS REPORT OF THE SPECIAL COMMITTEE ON STEEL COLUMNS AND STRUTS.*

To the American Society of Civil Engineers:

The Special Committee "to consider and report upon the design, ultimate strength, and safe working values of steel columns and struts", presents the following report of progress.

Some seventy columns on the programme of tests, which is being made for the Society by the Bureau of Standards, U. S. Government, S. W. Stratton, Director, have been tested. All the columns for both the light and heavy series have been fabricated and delivered at Washington.

During the past year, the Committee has held five regular meetings, most of these being called at Washington, in order to keep in close touch with the test programme, and a number of sub-committee meetings to consider special details.

Through W. H. Moore, M. Am. Soc. C. E., Chairman of the Sub-Committee on Built-up Columns of the Committee on Iron and Steel Structures of the American Railway Engineering Association, your Committee has kept in touch with their programme of tests.

The Committee has spent considerable time studying the tests that have been made, and has been able to suggest variations in methods which give additional information and improve the value of the records.

The methods of testing have been fairly well outlined, and as your Committee's final report will no doubt give emphasis to results rather than to methods, it is deemed wise at this time to report quite fully on this latter feature, in order that the members of the Society may become familiar with what is being done, and may be able to make suggestions to the Committee covering the interpretation of the results.

Testing Machine and Instruments.—All the tests have been made at the Bureau of Standards, with an Emery testing machine, which

* To be presented to the Annual Meeting, January 20th, 1915.

was authorized by Congress on March 4th, 1909, and was accepted in 1913. Its capacity is as follows:

Tension	1 150 000 lb.
Compression	2 300 000 lb.
Extreme length between heads:	
Tension	34 ft. 4 in.
Compression	33 ft. 1¾ in.
Clearance between screws	4 ft. 6 in.
Length of stroke of ram	5 ft.

It will be seen from Fig. 1 that it has two heads, one fixed and the other movable, on two straining screws, each 12 in. in diameter. The hydraulic ram which furnishes the pressure is in the movable head, and, as the stroke is only 5 ft., it is necessary to adjust this head for columns of different lengths. The weighing is done from the fixed head of the machine.

The weighing device, which is peculiar to the Emery machines, consists of a specially constructed hydraulic support in the fixed head of the machine, which is connected with a smaller hydraulic chamber in the scale case. The load on the test specimen is transmitted directly to the oil in the hydraulic support, and by hydrostatic pressure is transmitted to the hydraulic chamber which actuates the levers of the weighing scale. These levers are all of the plate-fulcra type, characteristic of all Emery testing machines.

The construction of the hydraulic support and chamber is such that a movement of 0.01 in. of the brass diaphragms is sufficient to register the full capacity of the machine. By use of these diaphragms and guiding rings, friction of the parts is eliminated.

The programme calls for all the tests to be made with square-ended columns, and this is done by providing cast-steel bearing blocks at each head, which bear directly against the columns. Considerable difficulty has been found in securing bearing blocks of sufficient accuracy, and it was necessary for the Bureau to go over all the blocks and dress them to a surface with a variation of not more than plus or minus 0.001 in.

For measuring the compressions on the longitudinal axis of the columns, compressometers were used, which consisted of a bar, fixed at one end to the column, and the other end connected with a micrometer gauge, which reads by estimate to ten-thousandths of an inch. This gauge was equipped with an electrical buzzer, which enabled the operator always to secure an equal contact. At the beginning of the series, wood bars were used, but, owing to the length of time taken in making a test, it was decided to substitute hollow steel bars, in order to avoid any possibility of changes due to moisture and temperature.

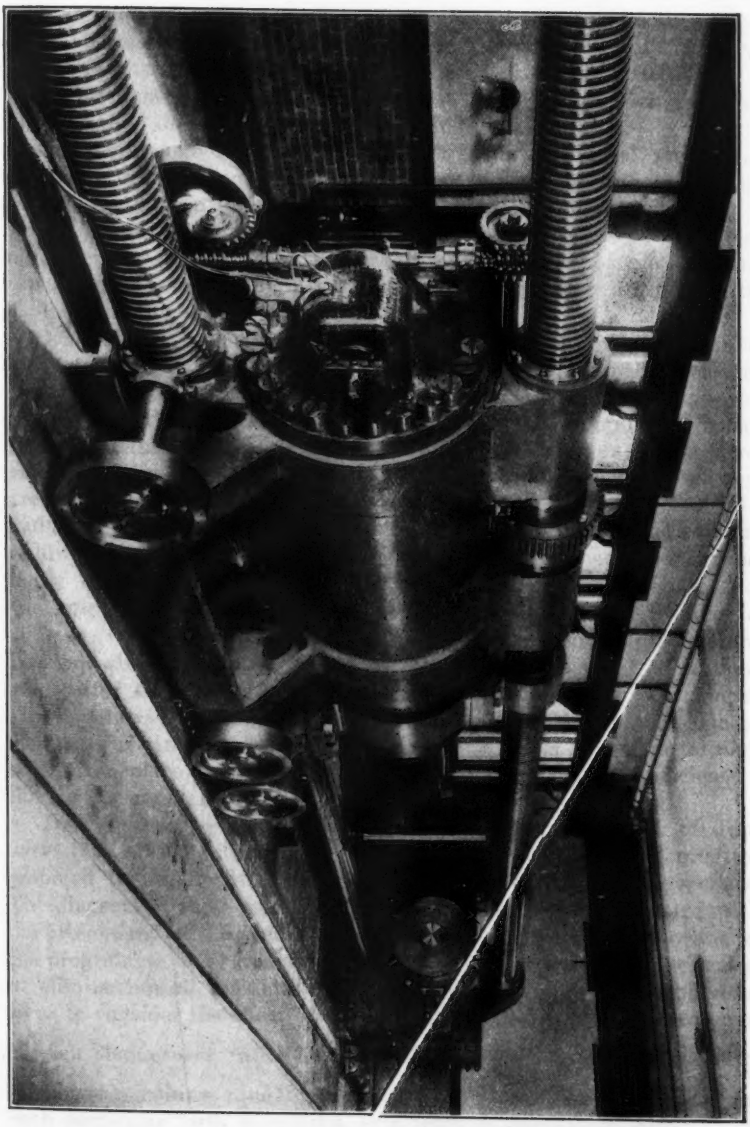

FIG. 1.—2 300 000-POUND TESTING MACHINE, BUREAU OF STANDARDS, WASHINGTON, D. C.

The local stresses were measured with a Berry strain gauge, which is made with a pair of Invar steel bars some 10 in. long, with a fixed point at one end and a movable point with a bell-crank at the other end. The horizontal arm is connected with an Ames dial gauge, which reads, with the multiplication of the bell crank, to 0.0002 in., and by estimating to 0.00002 in. The nominal length between the contact points of this strain gauge is 8 in.

The strain gauge measurement was made in the usual way, *viz.*, two holes were drilled, 8 in. apart, using a No. 55 drill, and then countersunk with a tool having an angle of about 110 degrees. This insures a good shoulder for the points on the strain gauge, which is highly essential for accurate work with this type of instrument. Experienced operators can secure very uniform readings within limits of plus or minus 0.0002 in.

Originally, the horizontal and vertical deflections of the column under test were measured with a piano wire, with a spring tension which was fastened to plugs set in each end of the column. Measurements were taken at the center by scales. It was found that when the ends of the column began to deflect, or warp, the local bends were transmitted to the wire, and this method was then improved by stretching the wire from a fixed frame below the column. The difficulty in securing accurate measurements from the wire to the column within limits of plus or minus 0.01 in. still remained, and it was finally overcome by abandoning the longitudinal wire entirely, and connecting the column at the center with two dial gauges reading to 0.001 in., which were supported on frames, independent of the column. Tension wires perpendicular to the longitudinal axis of the column transmitted the horizontal and vertical movements to the two gauges. Two operators were employed in manipulating the gauges, and, due to the length of time required to read these, some slight flow of metal may have taken place during the reading, but this was hardly sufficient to change the general result.

Test Columns.—The Progress Report of the Committee, of January 15th, 1913,* shows the column sections which the Committee proposed to use, together with the chemical and physical properties. The diagram of these sections and the properties are incorporated with the present report. In addition, it should be noted from this report that the programme was "arranged with the intention, as far as practicable, of eliminating all variables except that of form", and was subdivided so as to consider the effect of light and heavy sections. Three columns of each slenderness ratio, 50, 85, and 120 of $\frac{L}{R}$, were provided for all shapes, making nine light sections and nine heavy sections, for each particular form of column, or a total of 144 test columns.

* *Proceedings*, Am. Soc. C. E., for February, 1913.

In addition to these, the Bureau of Standards has provided eighteen columns of Bethlehem H-sections, and eighteen columns of Carnegie 6-in. and 8-in. H-sections.

TABLE OF CHEMICAL AND PHYSICAL PROPERTIES FOR SPECIAL SPECIFICATIONS FOR UNIFORM QUALITY STRUCTURAL STEEL FOR COMPARATIVE COLUMN TESTS FOR THE BUREAU OF STANDARDS, U. S. GOVERNMENT.

Material.—Basic open-hearth structural steel.

Chemical.—Uniformity is paramount, and must be aimed for.

Carbon.—The percentage of carbon must not vary more than just to insure the desired physical properties in required sections of material.

Manganese	0.40% min. and 0.50% max.
Phosphorus	0.00% min. and 0.03% max.
Sulphur	0.00% min. and 0.04% max.
Silicon	0.00% min. and 0.10% max.
Nickel	0.00% min. and 0.05% max.
Chromium	0.00% min. and 0.05% max.
Copper	0.00% min. and 0.03% max.
All possible others	0.00%

Physical.—The desired physical properties must be aimed for.

Ultimate tensile strength	Desired, 60 000 lb. per sq. in. (may vary 1 500 lb. either way).
Elastic limit (yield point)	Desired, 38 000 lb. per sq. in. (may vary 1 000 lb. either way).
Elongation in 8 in.	Desired, 28% (may vary 2% either way).
Reduction in area	Desired, 56% (may vary 4% either way).
Character of fracture	Silky, cup.
Cold bend without fracture	180°, flat, on itself.

During the rolling of the material at the mill, and the fabrication at the shop, the inspectors of the Bureau of Standards investigated the various processes, making notes of the different conditions to which the material was subjected. Care was taken that the material met the rigid specifications, and although some variations were allowed, it was only with the special permission of the Committee.

In addition to the material required for building the columns, the Bureau of Standards ordered additional pieces, 5 ft. long, of each shape and from each melt, so as to have an extra lot of unworked material on hand for special physical and chemical tests. The physical and chemical tests were first made on all shapes by the manufacturer, and

FIG. 2.

were then checked at the laboratory of the Bureau of Standards, at Pittsburgh.

It will be noted from the diagrams (Figs. 2 and 3) showing the cross-sections of the columns that the rivets were all of standard size, the smallest being ½ in. and the largest ¾ in. in diameter, and the rivet spacing called for four diameters throughout the total length of the columns. It was the intention of the Committee to over-rivet the sections, so as to insure the parts acting together as a whole. So far, in no case has a failure occurred due to a bulging of the material between rivets. Where the specimens have been compressed, in order to emphasize the method of failure, the rivets in all cases have remained tight.

In general, the shop work may be described as being uniformly good, and better than the average commercial grade. The ends were dressed square to the longitudinal axis of the column, but in almost all cases it was found necessary to re-dress them, owing to the fact that the ordinary commercial milling machine gives too rough a cut to insure complete bearing over the whole surface of the end cross-section of the column. After the test column was placed in the machine, special attention was given to insure a uniform bearing by applying loads of about 1 000 lb. per sq. in.

The investigation of the test columns developed variations in their sectional areas, these amounting, in extreme cases, to as much as 4% from the nominal area. In order to determine the correct area, the shapes were first calipered at the ends of the columns, and the variations noted. Prints of both ends were taken by blacking the ends and pressing white paper against them. The area was then determined by running a planimeter around the inside and outside perimeters. Finally, the column was weighed, the weight of the rivet heads was deducted, and the area was determined by the specific gravity of the material. This area, after being compared and checked with the results of the other two methods, was adopted as the correct one to be used in determining the unit loadings. When the column was put in the machine, before being tested, it was carefully examined for loose rivets, scale, or any other conditions which might affect its strength, and, during progress of the tests, rivets were tried and any scaling was noted. After the column was placed in the machine, a nominal load, of sufficient amount to insure its being held to the proper bearings, was applied, and the compressometers were attached. For the $\frac{L}{R}$ ratio of 50, 85, and 120, the test pieces ran on an average of 10, 16, and 23 ft. long, and the compressometers were arranged respectively with bars 50, 100, and 150 in. long. The two tests given* will indicate the details of applying the loads, and, as stated before,

*The details of these tests will be given later.

Make three columns of each length for all shapes

FIG. 3.

after each increment of 1 000 lb. per sq. in. had been applied, sufficient time was given to read the various strain gauges.

Failure of the column was first indicated by the dial gauges, which registered a rapid increase of the deflection at the center, and by the unbalancing of the scale beam, which showed a falling off of resistance to compression. With the exception of some additional scaling, the column at this time showed no apparent change, and the pressure could be maintained for several minutes before it had a perceptible bend.

As soon as the maximum loading was reached, the instruments were taken off, and one column of each series of three was further compressed, so as to emphasize the failure, and a photograph was taken to indicate how the column failed.

Methods of Testing.—After the material was ready for the beginning of the programme of testing, a conference was held between the physicists of the Bureau of Standards and a Sub-Committee of the Column Committee as to the methods of applying the loads and measuring the strains. A general outline of the instructions to the Engineer in Charge was agreed upon, and this outline is given below. Thus far it has not been necessary to make any marked changes in the methods. On certain tests, variations have been introduced, at the request of the Committee, or at the suggestion of the physicist, but, thus far, these have not produced enough variation from the general result to warrant their continuance.

Outline of Instructions for Testing.

Columns shall be weighed and gauged for sizes before being tested. In addition, inspection shall be made to determine the condition of the riveting, in order to see that the pieces are properly drawn together, especial note being made of any local conditions where the riveting has failed to do this. Observations should also be recorded where the pieces at the ends of the members have been bent. General alignment, waves in pieces or in the column as a whole, kinks, or any other special condition should be noted.

The ends of the columns shall be dressed flat to reduce the amount of shimming to a minimum.

The two longer series of columns, that is, those of 85, and $120\frac{L}{R}$ shall be counterweighted at the middle by an amount equal to one-half of the total weight of the column.

Strain gauge measurements along the length of the column, at points from 8 to 10 in. apart, shall be made at the center of the column and near both ends. The gauge points at the ends shall be placed far enough away to avoid effects of local distortion due to the taking up of the stresses. These strain gauge measurements shall be

made at each of the four corners of the column and at the center of the webs and flanges. Special shapes, such as the Z-bar and bulb angle shape columns, may require variations from this general rule in order to determine the variation in stress in the different parts of the column.

Compressometer measurements shall also be made on longer lengths, of from 50 to 150 in., in order to check the short strain gauge measurements. Four of these will be made on each column—two on the corners and one on the center of the flange, and one on the center of the web.

Deflection observations shall be made on the horizontal and vertical movements at the middle of the length of each test piece.

The condition of the cross-section of the column shall be determined by calipering the two open sides before applying the initial load, and at intervals of loading of 5 000 lb. per sq. in., in order to determine any change in the shape of the cross-section. This shall be done in as many places as may be necessary.

Initial loads of 1 000 lb. per sq. in. each shall be applied, and compression loads of 5 000, 10 000, and 15 000 lb. per sq. in. each, returning to the initial load and determining permanent sets; from 15 000 lb. proceeding with increments of 1 000 lb. per sq. in. each, determining permanent sets after loads of 20 000 and 25 000 lb. per sq. in. Also at 30 000 lb. per sq. in., if these several loads are reached before the column fails.

Horizontal and vertical deflections of the columns shall be observed at the time the longitudinal compressions and sets are measured. The general direction taken by the column when it fails, and whether due to deflection as a whole or local buckling, shall be noted.

Careful observations shall be made where the column first begins to scale, also the lines of scale. After failure, record the conditions of the rivets around the distortion points to see if any of these rivets are loose.

After the ultimate load has been reached, at least one column of each cross-section and length shall be compressed, to emphasize the manner of failure.

In general, photographs shall be taken of one column of each cross-section and length when the ultimate load has been reached, and in addition a photograph of each column on which the failure has been emphasized.

Examples of Tests.—The Committee gives the record of two of the tests, *Nos. 30 and 54, which contain the information as furnished by the Bureau of Standards.

A question arose as to the tendency of the material to flow under load, and in order to secure information on this point, a special time

* On account of the drawings required, the diagrams for these tests could not be given with the report; they will be reproduced later.

test was inaugurated. This is given as No. 54, where it will be seen that various loadings were applied and then held while the compressometers were read at intervals of 5 min. until the flow of the metal ceased. Although the results are interesting, and might be a matter of speculation in beginning a new programme, the variation in the failure point from similar columns does not seem to show enough difference to warrant any extensive carrying out of time tests in the present programme.

Considering the magnitude, both in the number of tests and the size of the columns, the present programme is being carried out with refinements which have never before been equalled. This is largely due to the enthusiastic co-operation of Dr. G. R. Olshausen, the Physicist in charge, and the cordial support of Dr. S. W. Stratton, the Director of the Bureau of Standards.

At the present time, less than one-half of the tests have been completed, and as it will be necessary to study the whole programme in order to correlate the results, the Committee makes this progress report.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

PROGRESS REPORT OF THE SPECIAL COMMITTEE TO INVESTIGATE THE CONDITIONS OF EMPLOYMENT OF, AND COMPENSATION OF, CIVIL ENGINEERS.

To the American Society of Civil Engineers:

The Special Committee appointed by the Board of Direction in January, 1913, "to investigate the conditions of employment of, and compensation of, civil engineers throughout the country; to collect statistics and data in reference thereto, and to report the results of such investigation to the Society", submitted a Progress Report to the Annual Meeting in January, 1914, and the Committee was continued.

Since the submission of this report the untimely death of its Chairman, Mr. Alfred Noble, whose loss was so generally deplored, has deprived the Committee of the advice of one whose knowledge and broad interest in the members of the Engineering Profession were of especial value in carrying out the work delegated to the Committee.

The Progress Report already submitted describes the methods adopted to secure information. These methods have been continued, but an effort has been made to reach a larger proportion of the membership of the Society. The Progress Report was based on information received from 3 638 members in various grades. On May 22d, 1914, a second circular was sent out, to which 1 240 replies were received; of these, 1 158 gave information which could be availed of, bringing the total number of usable replies to 4 796, which is two-thirds of the entire membership of the Society at the time the second circular was mailed. Inasmuch as it is impossible to identify those who have replied, there is no way in which the remaining members of the Society can be requested to furnish information, unless the entire membership is again circularized.

The information given in all the replies has been carefully analyzed under the direction of the Secretary, and has been incorporated

in a diagram, Plate XL, similar to that used in the first report of the Committee, and the new curves, while corresponding quite closely with those already published, are naturally more uniform and are believed to be more representative.

The irregularities in the curve representing the average yearly compensation have been generally reduced, although at some points they have been emphasized. For instance, although returns from engineers having 29 years of professional experience have been increased from 44 to 52, and although the maximum and minimum compensation remain the same, the eight additional replies have raised the average from $9 315 to $9 716, while at the next point on this curve, representing 30 years of active experience, although the maximum remains the same, there is a new minimum of $500, yet the average compensation has been increased from $5 281 to $5 346. Again, at 38 years, a new maximum, $10 000 greater that that formerly reported, has, with the same minimum, raised the average from $6 746 to $8 106; while at 39 years, where the maximum was and is $10 000, and the minimum $1 000, five additional replies have decreased the average from $4 600 to $4 329.

In the first report of the Committee reference was made to an attempt to draw a curve representing the compensation received by the middle man, but such a curve was not included in the diagram. Such a curve has been included in the diagram now submitted, Plate XL, and the Committee considers it worthy of special study.

Believing that the variation of compensation with the character of employment should be shown, a diagram, Fig. 1, has been prepared indicating the average compensation paid by the National Government, States, Municipalities, Technical Schools, Railroads, and Private Corporations and Companies, as well as the incomes of Consulting Engineers and Engineering Contractors. Inasmuch as the number of replies for each year of experience was relatively small, and might therefore be misleading, they have been grouped in 5-year periods, and the resulting curves are believed to be of interest and value. They indicate that the salaries paid by the National Government, States, Cities and Technical Schools, including in the last receipts from private practice, while closely corresponding with those paid by railroad companies during the first 20 years, are materially less after that period; that other corporations and private companies pay considerably higher salaries, and that the largest incomes are those of consulting and contracting engineers. That the curve showing the incomes of contracting engineers reaches its highest point at 30 years is probably due to the fact that it is only about 30 years ago that engineers became contractors to any considerable extent, or possibly to the fact that their success enables them to retire from active work at a relatively early age.

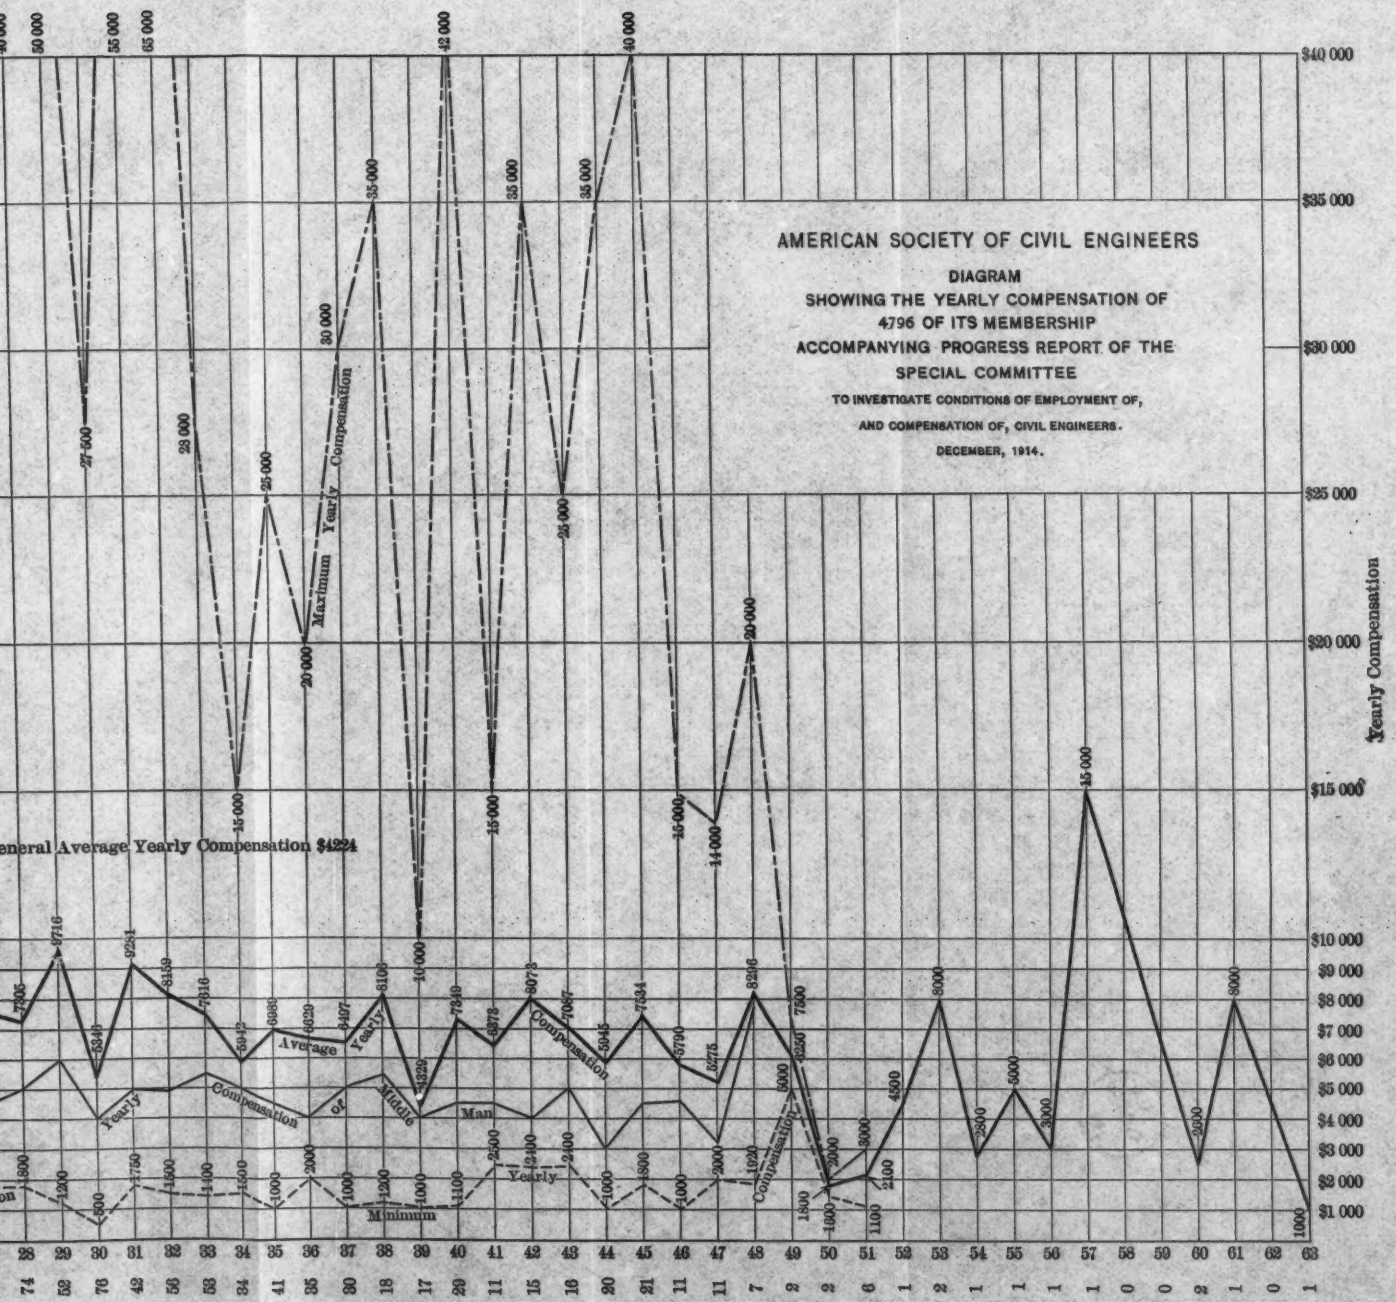
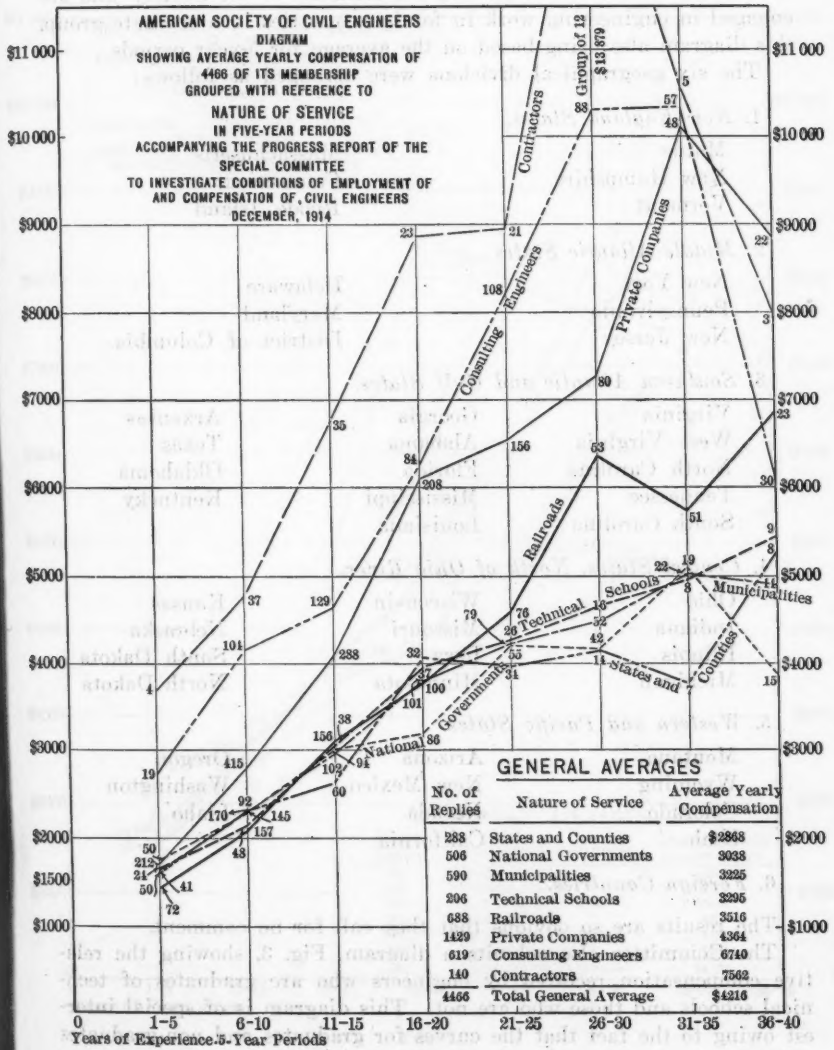
PLATE XL.
PAPERS, AM. SOC. C. E.
DECEMBER, 1914.
PROGRESS REPORT OF
SPECIAL COMMITTEE TO INVESTIGATE
THE CONDITIONS OF EMPLOYMENT OF, AND
COMPENSATION OF, CIVIL ENGINEERS.





GENERAL AVERAGES

No. of Replies	Nature of Service	Average Yearly Compensation
288	States and Counties	$2868
506	National Governments	3033
590	Municipalities	3225
206	Technical Schools	3295
688	Railroads	3516
1429	Private Companies	4364
619	Consulting Engineers	6740
140	Contractors	7562
4466	Total General Average	$4216

FIG. 1.

A diagram, Fig. 2, has been made showing the compensation received, arranged in geographical groups, using five different sections of the United States and placing the members of the Society who are engaged in engineering work in foreign countries in a separate group, this diagram also being based on the average for 5-year periods.

The six geographical divisions were arranged as follows:

1. *New England States.*

Maine	Massachusetts
New Hampshire	Connecticut
Vermont	Rhode Island

2. *Middle Atlantic States.*

New York	Delaware
Pennsylvania	Maryland
New Jersey	District of Columbia

3. *Southern Atlantic and Gulf States.*

Virginia	Georgia	Arkansas
West Virginia	Alabama	Texas
North Carolina	Florida	Oklahoma
Tennessee	Mississippi	Kentucky
South Carolina	Louisiana	

4. *Central States, North of Ohio River.*

Ohio	Wisconsin	Kansas
Indiana	Missouri	Nebraska
Illinois	Iowa	South Dakota
Michigan	Minnesota	North Dakota

5. *Western and Pacific States.*

Montana	Arizona	Oregon
Wyoming	New Mexico	Washington
Colorado	Nevada	Idaho
Utah	California	

6. *Foreign Countries.*

The results are so obvious that they call for no comment.

The Committee also submits a diagram, Fig. 3, showing the relative compensation received by engineers who are graduates of technical schools and those who are not. This diagram is of special interest owing to the fact that the curves for graduates and non-graduates follow each other very closely for the first 15 years. The graduate engineer appears to have an advantage from that time on to about 45 years, when the curves again come together.

FIG. 2.

The average yearly compensation of 1 998 graduates having an experience of from 2 to 15 years is $2 756. The average yearly compensation of 614 non-graduates having an experience of the same length is $3 154. The average yearly compensation of 1 394 graduates having an experience of from 16 to 50 years is $6 328. The average yearly compensation of 719 non-graduates having an experience of the same length is $5 359. This may be due to the fact that the preparation of the graduate engineers represented by that part of the curve between the fifteenth and forty-fifth years was more thorough in the fundamentals of engineering education, and that, whatever may have been their compensation in comparison with that of non-graduates for the first 15 years of their professional life, this thoroughness of preparation shows its effect from that time onward. It may be that among the non-graduates of technical schools only the most ambitious men apply for membership in the Society. Thinking that the non-graduate members of the Society might be older men, the Committee has requested the Secretary to furnish it with figures showing the ages of the graduate and non-graduate engineers whose returns supplied the data for the first 15 years of the curve.

These are as follows:

Years of experience.	Average age of graduates.	Average age of non-graduates.
2	24.8	27.4
3	25.7	25.3
4	27.2	25.6
5	28.4	27.7
6	29.2	27.8
7	30.1	29.9
8	31.2	29.8
9	31.9	31.0
10	32.9	32.3
11	33.6	33.2
12	34.4	34.8
13	35.6	35.7
14	36.6	35.8
15	38.0	37.5

It appears from these figures (which begin at the second year for the reason that non-graduates are not eligible for the grade of Junior for the first year of their experience) that the average age of the non-graduates is slightly less, instead of greater, than that of the graduates.

The replies from engineers having more than 50 years of experience are so few, and the information given by them is of so little significance, that it has not been included in any of the diagrams except that giving all the returns without classification.

FIG. 3.

Other conclusions may be drawn from the information shown by the diagrams, and will probably be brought out in comments which may be made on the report.

Discussions of the first report of the Committee appeared in the *Proceedings* for February, April, May, and October, 1914. While the Committee does not believe it necessary to review these discussions at length, some of the comments and suggestions will be referred to briefly. The opinion was expressed that if curves had been prepared which excluded the upper and the lower 5%, and the upper and the lower 10%, the result would have been more nearly representative of the average compensation of civil engineers; it is doubtless true that the curves would have been more regular and somewhat lower, but the Committee believes that it should take account of the clearly exceptional man as well as of the average man. It was also stated that if those who failed to respond had been heard from, the averages would have been materially lower. This opinion does not appear to have been confirmed by the 1 158 replies to the second circular, which have made little change in the curve, except to render it somewhat more uniform.

Another suggestion was that, if all professional incomes of more than $15 000 a year had been excluded, the result would have more nearly represented actual conditions, but the Committee believes that this would have been distinctly unfair and misleading. The majority of those who contributed to the discussion expressed the belief that the statistics should include all engineers who could be reached, and should not be confined to members of the Society, and that the curves given represent a select list and the ideal rather than the real compensation received by engineers, one of the reasons for this being that members of the Society who receive very small salaries are sensitive about making a return. The Committee believes, however, that in a canvass of the entire Engineering Profession the same reluctance, of low salaried and unsuccessful men, to answer the questions would have been just as conspicuous.

The Committee believes that this Society is the representative body of civil engineers in this country and that information collected from its members is the kind of information that the members of the Society wish. In order, however, to meet the evident desire of many members of the Society for statistics which will include those outside its membership, the Committee proposes to endeavor to secure such information and to make a further classification based on actual age as well as the number of years in engineering practice, while it is also proposed to secure information indicating the proportion of time when engineers are out of employment. In securing information concerning engineers who are not members of the Society, the Committee will be obliged to use such data as it can secure from railroads,

municipalities, and other organizations or individuals employing engineers, and from technical schools which have compiled statistics concerning their graduates and former students. The Committee realizes that the collection of this kind of data will be much more difficult than the work which it has already done and that the results will be less conclusive and less accurate than those herewith presented. If it is the pleasure of the Society to continue the Committee for another year, this work will be undertaken, and, in this event, the Committee hopes that members of the Society will voluntarily send to it any information they may have which will be of assistance in this work, or that such data be presented in the form of discussions of this report.

The Secretary of the Society has prepared the forms used for the collection of data, and has, with the assistance of members of his staff, tabulated the results and prepared the diagrams which accompany this report, and the Committee wishes to record its appreciation of the careful and thorough manner in which this work has been done.

Respectfully submitted,

NELSON P. LEWIS,
Chairman.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

STRESSES IN WEDGE-SHAPED REINFORCED CONCRETE BEAMS.

Discussion.*

By Messrs. A. C. Janni and William Cain.

Mr. Janni.

A. C. Janni, M. Am. Soc. C. E. (by letter).—In a recent paper by William Cain, M. Am. Soc. C. E., entitled "Stresses in Wedge-Shaped Reinforced Concrete Beams", there were enunciated formulas for computing the maximum compressive stresses in concrete, as well as the maximum tension in steel. These formulas, together with the assumptions underlying them, are of such a nature as to lend themselves to a critical study which, the writer thinks, may not be entirely devoid of interest.

Leaving out of consideration the points of minor importance in this paper, it is thought expedient to confine this critical analysis to the principal ones. In the first place, in dealing with the problem referred to, the author, in simplifying a certain expression, uses a method somewhat objectionable.

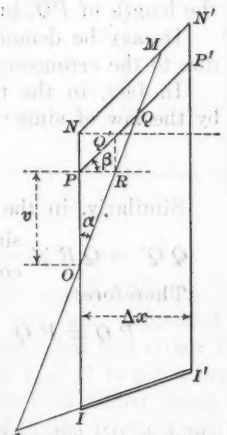

Fig. 16.

Fig. 16 is similar to the author's Fig. 2 (*b*), and shows two parallel sections, NI and $N'I'$, of a wedge-shaped reinforced concrete beam. Let O be the position of the neutral axis of the section, NI, and MJ the position of NI after stress; the angle of rotation being α.

A foot-note on page 748 of the paper is as follows: "In the triangle, POQ, by the law of sines, $PQ = \frac{v \sin. \alpha}{\cos. (\alpha + \beta)}$. As α tends toward zero, this approaches $\frac{v\,\alpha}{\cos. \beta} = v\,\alpha \cos. \beta$."

* This is a continuation of the discussion on the paper by William Cain, M. Am. Soc. C. E., published in *Transactions*, Vol. LXXVII, p. 745.

Mr. Janni.

This simplification is not correct. A mathematical simplification cannot be performed on a mathematical abbreviation. Now, cos. $(\alpha + \beta)$ is purely a symbolical expression, and one cannot operate on it without developing first the expression itself.

Cos. $(\alpha + \beta)$ is not an actual value, and can be an actual value only when α and β have assigned numerical values, which is not so in this case.

The correct simplification of this expression is represented by:

$$P\,Q = \frac{v\,\alpha}{\text{cos. } \beta - \alpha \text{ sin. } \beta}$$

which cannot be simplified further, when one considers that $v\ \alpha$ and α sin. β are infinitesimals of the same order, and that the previous expression is not final but must pass through an integration, as is shown in the paper.

It may be readily seen that the author, with that simplification, did not find the value of PQ, as he thinks, but of a part of it only.

In fact, in the triangle, POR, Fig. 16, α being very small, $PR = \alpha\ v$; and RQ' being parallel to OP, or perpendicular to PR, $PQ' = \frac{\alpha\ v}{\text{cos. } \beta} = \alpha\ v \text{ sec. } \beta$; therefore, the value $\alpha\ v$ sec. β does not represent the length of PQ, but that of PQ', which is a part of PQ.

It may be demonstrated also that the difference, QQ', is precisely due to the erroneous simplication.

In fact, in the triangle, PRQ, with the notations in Fig. 16 and by the law of sines:

$$R\,Q = \frac{v\ \alpha \text{ sin. } \beta}{\text{cos. } (\alpha + \beta)}.$$

Similarly, in the triangle, RQQ':

$$Q\,Q' = Q\,R \times \frac{\text{sin. } \alpha}{\text{cos. } \beta} = \frac{\text{sin } \alpha\ \ v\ \alpha\ \text{ sin. } \beta}{\text{cos. } \beta\ \text{ cos. } (\alpha + \beta)} = \frac{\alpha^2\ v}{\text{cos. } (\alpha + \beta)} \text{ tan. } \beta.$$

Therefore:

$$P\,Q = P\,Q' + Q'\,Q = v\ \alpha \text{ sec. } \beta + \frac{\alpha^2\ v \text{ tan. } \beta}{\text{cos. } \beta - \text{sin. } \beta\ \alpha}$$

$$= \frac{v\ \alpha}{\text{cos. } \beta - \text{sin. } \beta\ \alpha}$$

which is the value of PQ, as previously stated by the writer.

It seems to the writer that in the paper referred to, as well as in its closure, there is a confusion of conception in regard to the behavior of a toe-beam, a dam, and counterfort.

A dam, when properly built, may be designed,* as far as the maximum compressive stress is concerned, considering a vertical element of it 1 ft. thick and assuming that, for a certain height, it is a vertical

*F. Platzmann, "Ueber den Querschnitt der Staumauern." Leipzig, 1908.

beam, fixed at the base and free at the top, under the actions of its dead load and of the hydraulic pressure against its up-stream face. Mr. Janni.

The writer does not think it necessary to enter into any analysis concerning the design of a dam; this important kind of construction now has a rather complete theory, which does not need any workable formula for its design.

A toe-beam, supporting a retaining wall, etc., may be designed as a horizontal beam, if its shape is as in Fig. 1,* fixed at one end and free at the other, under the actions of the vertical reaction of the soil and of the friction developed along the base line.

Concerning now the case of a counterfort, as shown in Fig. 17, the writer does not understand on what assumptions it is designed as a beam.

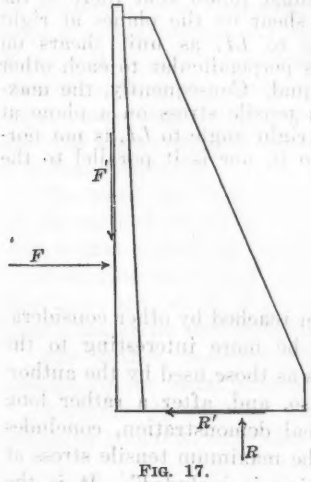

FIG. 17.

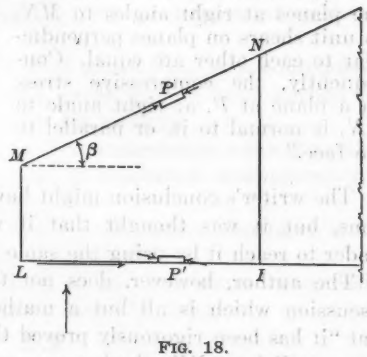

FIG. 18.

If a beam, as commonly understood, means a solid having one dimension a great deal larger than the other two, and supported or fixed at both ends, or fixed at one end, having the other end either free or supported, it is clear that the solid shown in Fig. 17 is not a beam.

That solid is under the actions of the horizontal thrust along its height, as well as of the reaction at the base and of the friction against the soil; there is no moment at the base which would entail the fixed-end hypothesis.

The author is quite right in demonstrating that the maximum compressive stress along *MN*, Fig. 18, is parallel to *MN*, and the writer begs leave to borrow that demonstration, in order to show that in the same beam the maximum tensile stress is not parallel to *LI*, if friction is included.

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 745.

Mr. Janni.

For convenience the writer will quote the author's demonstration, and alongside of it will place the demonstration supporting his own statement:

Author's demonstration that the direction of the stresses at any point of the upper surface is parallel to *MN*.

" * * *; for, consider a small rectangular parallelopiped of the concrete at *P*, with faces parallel and perpendicular to *MN*. There can be no shearing stress on *MN*, as no part of the beam extends above *MN* to produce shear, and there is no external force acting on *MN* except the atmospheric pressure, which does not exert any friction on the face. It must follow that there can be no shear on the planes at right angles to *MN*, as unit shears on planes perpendicular to each other are equal. Consequently, the compressive stress on a plane at *P*, at right angle to *MN*, is normal to it, or parallel to the face."

Writer's demonstration in support of his statement that the maximum tensile stress at any point of *LI*, is not parallel to *LI*.

In fact, consider a small rectangular parallelopiped of the concrete at *P'*, with faces parallel and perpendicular to *LI*. There is shearing on *LI* developed by the friction due to the soil reaction.

It must follow that there is the same shear on the planes at right angles to *LI*, as unit shears on planes perpendicular to each other are equal. Consequently, the maximum tensile stress on a plane at *P'* at right angle to *LI*, is not normal to it, nor is it parallel to the face.

The writer's conclusion might have been reached by other considerations, but it was thought that it would be more interesting to the reader to reach it by using the same truths as those used by the author.

The author, however, does not think so, and, after a rather long discussion which is all but a mathematical demonstration, concludes that "it has been rigorously proved that 'the maximum tensile stress at *I* is parallel to *NI*' whether or not friction is included". It is the writer's opinion that this demonstration does not demonstrate anything as to the direction of the tensile stress along *LI*.

It is difficult to understand the purpose of the demonstration concerning the well-known continuity of stresses in a beam, brought forth so elegantly by Culmann by means of his "circular diagrams."

When it is assumed that all compressive stresses, with respect to the section, *NI*, are parallel to *MN*, it is going too far.

From the description in the paper of the behavior of those stresses along *NI*, the writer has the impression that the author, perhaps, refers to "principal" or "ideal stresses," instead of bending stresses, as usually called.

If the writer's assumption is correct, then it cannot be assumed that they are parallel, neither can it be assumed that, with respect to the

Mr. Janni.

section, *NI*, plane sections before stress remain plane sections after stress.

Theory clearly shows the behavior of those stresses and the shape of *NI* after stress.

Fig. 9* shows the lines of the ideal or principal stresses in the toe, *MNIL*, under the action of the vertical reaction. This figure may be obtained, for instance, by cutting Fig. 13† at 4-4 or 5-5.

Obviously, those stresses, with respect to *NI*, are not altogether compressive stresses, but, at each point of *NI*, the component of it, normal to *NI*, will be the compressive stress, and the component of it, parallel to *NI*, will be the shear at that point; this being quite an elementary matter.

Speaking of compressive stresses not being normal to a cross-section is nonsense. Furthermore, the stretching of the fiber, *PP'*, with respect to the section, *NI*, is a function of the modulus of elasticity, *E*, as well as of the coefficient of Poisson, and not of the modulus of elasticity, *E*, only. However, whatever may be the meaning of the paper concerning the nature of those internal forces, the writer thinks that the author entered a rather difficult field when he tried to devise a workable formula.

The mere fact that the shear at *N* is never zero, as a consequence of the method of design shown in the paper, should have warned the author that something was wrong with his method.

Following his method, the shear at *N* is a maximum when $\beta = 45°$; that is to say, at *N*, if $\beta = 45°$, there is maximum compression and maximum shear simultaneously.

The author, however, states: "Above the neutral surface, it decreases, by the usual parabolic law, to zero at *N*."

Formula 8‡ for the computation of the maximum compressive stress in concrete, may also be written (see Fig. 10§):

$$f_c = \frac{2M}{by\left(h - \frac{1}{3}y\right)\cos.^2\beta}$$

where: f_c = maximum compressive stress in concrete,
M = external moment,
β = angle of inclination of the top of the beam to the horizontal,

the other letters having the meaning shown in Fig. 10.

This formula shows that, if *N* keeps a constant section, and *MN* rotates about *N*, the angle, β, increasing gradually, while *M* keeps constant also, the *NI* becomes weaker and weaker.

---

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 765.
† *Loc. cit.*, p. 771.
‡ *Loc. cit.*, p. 751.
§ *Loc. cit.*, p. 758.

Mr. Janni.

Neither does the limitation of β to 60° for the permissible use of the author's formula prevent the foregoing absurd conclusion; nor should his remark, that the line, *MN*, should be extended to the left of the section, *NI*, be taken into serious consideration.

It is well known that the left part of that solid remains there only and solely in order to carry the action of the external force, which is acting on it, on the section, *NI*; provided the acting external force has constant intensity, direction, and distance from the section, *NI*. Its moment (external moment) will not change in the least its value, whatever be the geometrical shape of the solid on the left of *NI*.

If the author, in dealing with wedge-shaped beams, as in Fig. 18, had considered the cross-section at *N* normal to *MN*, instead of parallel to the acting forces, he would have avoided absurdities, and would have seen that, after all, theory is not "plainly inadequate".

The author says:

"Suppose a reinforced concrete T-beam, Fig. 15, with an inclined flange; would not a designer naturally take the compressive stresses in the flange as acting parallel to its surface?"

To this the writer would like to reply that a designer would take the compressive stresses, as the author says; but he would not consider those compressive stresses as acting on the vertical section, as shown in Fig. 15; if he did, he would be flatly wrong.

The case of a toe-beam, as in Fig. 18, is not one of bending only, but of bending and compression at the same time.

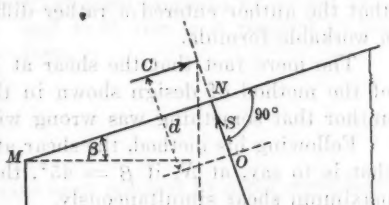

FIG. 19.

Fig. 19 shows how the vertical reaction, *R*, acts on a toe-beam. In this figure:

C = Component normal to NI = the intensity of compressive force acting on NI;

$C \times d$ = External moment of the compressive force, C, acting on NI;

S = Component parallel to NI = shear along NI.

It would be rather interesting to know what are the "mathematical difficulties in the way where" a section "is not parallel to the line of action of the loads."

The writer has reason to believe that, in the location of the neutral axis in a cross-section of a wedge-shaped beam, the elementary principles, which are the basis of such determination, have been ignored.

In fact, assuming that all stresses have the same direction and

that plane sections before stress will remain plane sections after stress, is the same as assuming that the stresses are proportional to the distances from the neutral axis; no matter what the common direction of those stresses may be. Mr. Janni.

In other words, the center of compression, being fixed in position, as well as the center of tension, the position of the neutral axis is fixed also, no matter what may be the intensity of the stresses (within the elastic limits) and their direction.

The center of compression, after all, is the antipole of the neutral axis with respect to the ellipse of inertia of the compressed part of the section, and the center of tension is the antipole of the neutral axis with respect to the ellipse of inertia of the part of the section under tensile stress.

This relation is purely a graphical one, and as long as the centers of compression and tension do not change their position, that of the neutral axis cannot change.

The statement, therefore, that the plain methods used to locate the neutral axis in a cross-section of a prismatic beam "are entirely inapplicable to a wedge-shaped beam" is quite incorrect. This remark, however, is purely incidental; because, in the case under discussion, the position of the neutral axis is determined either by an equation of the third degree, or by graphical methods.

Equation 3 (a quadratic in k), obtained by the author, should have warned him again that his theory was astray; for, a quadratic equation for determining the position of the neutral axis is obtained when it is a case of bending only; but, in the case of a reinforced concrete toe-beam, as in Fig. 18, as has been said already, there is both bending and compression at the same time.

WILLIAM CAIN,* M. AM. SOC. C. E. (by letter).—The writer is again indebted to Mr. Janni for a stimulating discussion in which he introduces some new points of view. Since the publication of his paper,† the writer has attacked the subject from another point of view and instituted a comparison of methods which leads to some results of interest. He intended to publish this independently, but it can also appropriately be given here in connection with Mr. Janni's further discussion. Mr. Cain.

Mr. Janni devotes much space to the expression, $P\ Q = \frac{v \sin. \alpha}{\cos. (\alpha + \beta)}$. According to the writer, as α tends indefinitely toward zero, this expression tends toward the value, $\frac{v\ \alpha}{\cos. \beta} = v\ \alpha \sec. \beta$. The writer is unable to catch Mr. Janni's viewpoint in objecting to this statement,

* Chapel Hill, N. C.

† *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 745.

Mr. Cain. Mr. Janni contending that cos. $(\beta + \alpha)$ does not tend to cos. β when α tends to zero. A number of proofs will be given, in the hope that one, at least, may meet his objections.

(1) From the unit circle, Fig. 20, in which, $P\ C\ M = \beta$, $M\ C\ N = \alpha$, cos. $(\beta + \alpha) = C\ A$, cos. $\beta = C\ B$, we see that as α tends toward zero, N approaches M, A approaches B, and $C\ A$ approaches $C\ B$ indefinitely, which proves that cos. $(\beta + \alpha)$ approaches cos. β indefinitely as α tends toward zero. Further, cos. $(\beta + \alpha) = C\ A$, is as much a "value" as cos. $\beta = C\ B$.

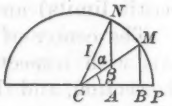

FIG. 20.

(2) Cos. $(\beta + \alpha)$ = cos. β cos. α — sin. β sin. α. As α tends toward zero, the right member tends toward cos. β — 0 = cos. β. Otherwise, sin. β sin. α is an infinitesimal and can be neglected in comparison with the finite first term cos. β cos. α, which by the same theory of infinitesimals can be replaced by cos. β.

(3) From Fig. 21, $R\ Q = O\ R$ tan. α, $P\ Q = R\ Q$ sec. $\beta = O\ R$ tan. α sec. β; therefore, as α approaches zero, Q approaches P, $O\ R$ approaches $O\ P$, and tan. α approaches α; whence $P\ Q$ approaches indefinitely the value,

$$O\ P.\ \alpha \text{ sec. } \beta = v\ \alpha \text{ sec. } \beta.$$

(4) Finally, take the expression deduced by Mr. Janni:

$$P\ Q = v\ \alpha \text{ sec. } \beta + \frac{\alpha^2\ v \text{ tan. } \beta}{\text{cos. } \beta - \text{sin. } \beta\ .\ \alpha}.$$

The last term, containing α^2 as a factor, is an infinitesimal of the second order in comparison with the preceding term having α as a factor; hence, by a well-known theory of infinitesimals, the last term can be omitted in comparison with the preceding, giving, as before, $P\ Q = v\ \alpha$ sec. β.

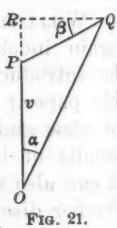

FIG. 21.

Turning now to the subject of principal stresses, the term "principal stress" in the case of beams subject to flexure, is to be understood in the usual sense as defined in the textbooks. Thus, Morley,* in addition to the usual figure, showing the directions of the principal stresses at various points in a short prismatic beam of rectangular cross-section, gives the magnitudes of the principal stresses for all points in a vertical section where the shear is large. A figure corresponding to this, but to a larger scale, is given by Turneaure and Maurer.†

In the case of the wedge-shaped beam without reinforcement, Mr. Janni's Fig. 9‡ represents the directions of the principal stresses at

* "Strength of Materials," p. 138.
† "Principles of Reinforced Concrete Construction," Art. 46.
‡ *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 765.

the various points of the cross-section approximately, about as the writer would conceive them. It was because Mr. Janni identified these intermediate "principal stresses" with the writer's "intermediate bending stresses" that he objected. In the hope that the distinction may be defined clearly, an attempt has been made to draw the principal compressive stresses at various points on the section, *I N*, of Fig. 22 (3), from analogy to the figures of the textbooks referred to. The principal tensile stresses on *O N* are not drawn. The figure is supposed to represent part of the toe of a reinforced concrete beam, subjected to a load acting vertically upward. The upper part of the beam is supposed to make an angle, β, with the horizontal. Mr. Cain.

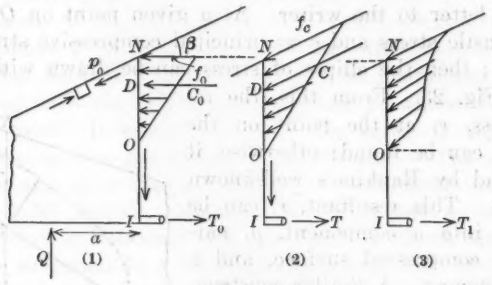

FIG. 22.

Professor O. H. Basquin,* has kindly sent the writer what he styles a "Rough Test of a Wedge-Shaped Glass Beam", with polariscope, to show the inclination of the principal compressive stresses with the horizontal at the points indicated in Table 2. The value of β was 15.5° and the small beam was subjected to a single vertical load about 3½ in. from the section where the measurements were taken. The entire vertical section was divided into fourteen equal parts, and the center of each (where the angle was measured) was numbered from the top down, consecutively, 1, 2, 3, ... The results are given in Table 2.

TABLE 2.

Point.	Angle.	Point.	Angle.	Point.	Angle.	Point.	Angle.
1	15.6°	5	17.7°	9	76.4°	13	89.2°
2	14.9	6	22.2	10	83.9	14	89.5
3	14.4	7	35.9	11	86.7		
4	15.9	8	60.5	12	88.0		

"The values given for angles away from center of beam may have an error of about half a degree with a larger probable error near the center."

* Northwestern University, Evanston, Ill.

Mr. Cain.

The results are very interesting. It will be observed that the angle first decreases slightly and then increases. For one-fourth of the way down, it is practically constant and nearly equal to β.

The writer's assumption as to his so-called "bending stresses" is shown in Fig. 22 (2). These stresses, for a given β, are all taken parallel to the upper surface, and increase regularly in going from the neutral axis, O, to N.

If, in Fig. 22 (3), the tensile principal stresses acting on $O\ N$ are supposed to be added, the relation between the state of stress in the revised figure (which represents all the stresses acting on the section, $I\ N$) and that given in Fig. 22 (2) can be shown by aid of the ellipse of stress in a manner kindly suggested by Professor H. A. Thomas,* in a recent letter to the writer. At a given point on $O\ N$, let $t =$ principal tensile stress and $c =$ principal compressive stress (at right angles to t); then the ellipse of stress can be drawn with t and c as semi-axes, Fig. 23. From this, the resultant stress, r, at the point on the plane, $I\ N$, can be found; otherwise, it can be found by Rankine's well-known construction. This resultant, r, can be decomposed into a component, p, parallel to the compressed surface, and a vertical component. A similar construction being supposed to be effected for each point of $O\ N$, the fundamental assumption made by the writer can be stated thus: the component of the resultant stress, r, parallel to the surface in compression, at any point of the reference plane, $I\ N$, is assumed to increase directly as the distance of the point from the neutral axis. The neutral axis may be defined as the line where the parallel component vanishes.

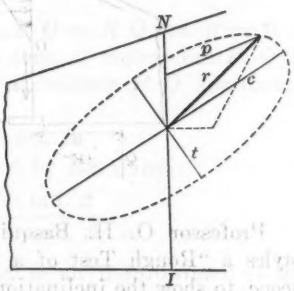

FIG. 23.

This is in agreement with the common theory of flexure for prismatic beams, which states that "the normal component of the resultant stress on the reference section, at any point, is assumed to increase directly as the distance of the point from the neutral axis."

This use by Professor Thomas of the ellipse of stress furnishes a scientific basis for the system of parallel stresses proposed, and shows very clearly that no one of the parallel stresses is a principal compressive stress, except at N, where the principal stress is parallel to the surface. Further, when this construction is supposed to be made for each point of $O\ N$, Fig. 22 (3), the result will be, not only the system of parallel forces, Fig. 22 (2), but, in addition, a vertical force acting downward along $N\ O$, equal to the sum of the vertical

* Rose Polytechnic Institute.

components referred to in connection with Fig. 23. This force, together with the sum of the vertical components of the parallel stresses, constitutes the total vertical shear on the part of the section under compression. As just shown, the parallel stress at some point, O, is zero, and if the hypothesis that plane sections, I N, remain such after strain is realized, then the original analysis shows (at least for a constant, E), that the linear law of variation holds, or the parallel stresses increase uniformly from O to N. Mr. Cain.

It thus appears that the system consisting of the uniformly varying parallel stresses of Fig. 22 (2), with the vertical force acting along N O, is the exact equivalent of the stresses shown in Fig. 22 (3), with the tensile principal stresses added. It follows that the moment of the system of Fig. 22 (2) about I (say), is exactly equal to the moment about I of the stresses of the other system. This tacitly assumes that the point, O, of Fig. 22 (2), as determined by the formula, is identical with the point, O, of System 3, where the parallel component is zero. It would seem that any error, in this particular, is mainly due to the hypotheses being inexact. The conservation of plane sections after strain, may not be sufficiently realized, particularly near N; besides, the modulus, E, is not a constant when β is not zero; for Poisson's ratio is really involved, since the interior fibers are subjected to stresses at right angles to their axes in addition to the longitudinal stresses. But Poisson's ratio is said to be very small for concrete $\left(\frac{1}{10}\text{ to }\frac{1}{8}\right)$, and the error resulting from ignoring it should be small. Of course, in place of the last two hypotheses, the formulas could all be derived from the one assumption of uniformly increasing stresses, but perhaps the results would not be so obvious.

It may be well to remark that p, in Fig. 23, is an oblique stress, per unit of area of the vertical plane, whereas the unit stress, f, of Fig. 22 (2) and of the formulas, acts normally to a plane perpendicular to the surface; therefore, $p \times 1 = f \cos.\ \beta$, or $f = p \text{ sec. } \beta$. Hence f varies with p and thus follows the linear law with p.

The writer will now try to make clear the term "intermediate bending stress" in connection, say, with a homogeneous toe-beam. In Fig. 23, if r is resolved into a vertical component and a component, p', the inclination of which to the horizontal at N is β, and which is then decreased according to some arbitrary law, gradually from β at N, to zero at I, as the point considered moves down the joint, the system of stresses, p', would constitute the system of "intermediate bending stresses." Below O (where $p' = 0$) the stresses would be tensile. Such a conception of "intermediate bending stresses" was entertained to try to bridge over the gap between the states of stress of reinforced and homogeneous toe-beams; it was not used, and is not necessary, in the development of the formulas, and it will be

Mr. Cain.

entirely eliminated from the discussion that follows. In this, a discussion of such experiments as are at present available will be given the better to estimate the degree of security of the formulas.

From the experiments on dams, discussed later, it seems highly probable that plane sections, $I\ N$, do not remain such after strain in the vicinity of N. In fact, the resistance there, to the left of $I\ N$, is less than for a prismatic beam of the height, $I\ N$. If so, the value of f_c, Fig. 22 (2), as computed from the formula, will be in excess, or the result will be on the side of safety, as originally claimed. Direct experiments on wedge-shaped beams could easily be made to decide as to whether the conservation of plane sections after strain is sufficiently realized; also to determine the neutral axis and the values of f_c and other parallel stresses near the surface. It is the writer's belief that some of the latter are nearly as large as the computed f_c and that the actual principal compressive stress at N is less than f_c as computed. In fact, if the latter statement is true, then certain stresses below N must be largely increased, so that the resisting moment about I may equal the constant moment of the external forces. As a comparison will ultimately be made between the results pertaining to the systems of stress shown in Fig. 22 (1) and (2), the first system (1) will now be examined. In this, the direct stress at N, f_0, due to bending (using Morley's term) acts horizontally, and is to be found by the well-known formula for a prismatic beam, just as if β was zero.

$$f_0 = \frac{2\,M_c}{k_0\,j_0\,b\,d^2}.$$

This formula is found in any of the textbooks on reinforced concrete, or it is given by Equation 12 of the writer's paper,* provided k_0 and j_0 denote the values of k and j for $\beta = 0$, the steel bars being horizontal. Since the moment of the external forces about I is exactly equal to the moment of the internal stresses about I, we can put $M = M_c$. For brevity, write,

$$\frac{2\,M_c}{b\,d^2} = \frac{2\,M}{b\,d^2} = c\,;$$

then the formula can be written,

$$f_0 = \frac{c}{k_0\,j_0}.$$

It was long ago pointed out, in the case of dams at least, that f_0 was only one conveniently chosen component of the resultant stress at N, which last acts parallel to the surface on a plane perpendicular to it. Call this principal stress p_0; then if f_0 is really the true

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 754.

normal unit stress on a vertical plane, it follows that $p_0 = f_0 \sec.^2 \beta$.* Mr. Cain.

Now, for large values of β, with M and therefore f_0 constant, it is seen that $p_0 = f_0 \sec.^2 \beta$ becomes very large, increasing indefinitely toward infinity as β approaches 90 degrees. As this is totally unreasonable, it must follow, for a given M, b, and d, that f_0 must decrease as β increases, so that $p_0 = f_0 \sec.^2 \beta$, shall remain within reasonable limits as β increases. Also since $\sec.^2 \beta$ is a continuous function when $\beta < 90°$, increasing with β, and since $p_0 = f_0$, for $\beta = 0$, is an accepted value, it seems very probable that f_0 decreases continuously as β increases from zero, the decrease being small for small values of β and becoming greater and greater as larger values of β are taken. This probability becomes a certainty when it is considered that the toe to the left of $I\ N$, Fig. 22 (1), is less resisting than a prismatic beam of the cross-section, $I\ N$, of the same length, and consequently the actual value of f_0 at N, for the toe, is less than that for the prismatic beam of the same length. This is easily realized, especially for large values of β, by supposing the toe to be cut out of the corresponding prismatic beam, when it is apparent that near N, there is less matter to resist horizontal forces to the left than to the right of $I\ N$, and the conservation of plane sections after strain, may not apply there.

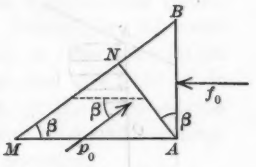

FIG. 24.

It appears, further, that the excess in the computed value of f_0, over the true value for the toe, should be very small near the truncated end of the toe, since the resistance, as regards bending of the toe and the corresponding prismatic beam (the common section, $I\ N$, being now near the end of the toe) are nearly equal. As the section, $I\ N$, Fig. 22, is taken farther from the end of the toe, the excess should increase and reach a maximum where the toe joins the stem.

The state of the horizontal stress on the vertical plane, $I\ N$, is probably as indicated in Fig. 25, the unit stress at N being less than the value of f_0 as computed by the foregoing formula, the unit stress then increasing for a little distance below N and then decreasing as O is approached, the sum of the moments of all the stresses on the cross-section about I being equal to M, as before. The unit stresses, a little below N, are thus greater than the ordinary theory would give, and plane sections, as $I\ N$, do not remain so after bending, otherwise the stresses would follow a linear law of variation from

* In Fig. 24, let $A\ N$ be at right angles to the surface, $M\ N$. Then, when $A\ N$ is regarded as infinitesimal, the stress on it is, $p_0 . A\ N = p_0 . A\ B \cos. \beta$, and its horizontal component is, $p_0 . A\ B \cos.^2 \beta$. For equilibrium of $A\ N\ B$, this must equal the horizontal stress on $A\ B = f_0 . A\ B$. On equating and solving, we find, $p_0 = \frac{f_0}{\cos.^2 \beta} = f_0 \sec.^2 \beta$, a formula that seems to be better known in Europe than in America.

Mr. Cain.

O to N. The same reasoning would indicate a similar modification in the state of stress shown in Fig. 22 (2), so that f_c, as computed by the formula, is in excess of the true value. It is to be hoped that direct experiments on wedge-shaped beams will soon be instituted to test these inferences. Lacking these, the experiments on india-rubber dams of Wilson and Gore and those on plasticine dams of Ottley and Brightmore* will be appealed to. From these experiments it was ascertained that the vertical unit stress on horizontal planes did not vary uniformly, the stresses near the down-stream face being generally less than corresponds to the law of uniform variation, the difference being practically nothing in the upper part of the dam and increasing as the foundation is approached, where it is comparatively large.

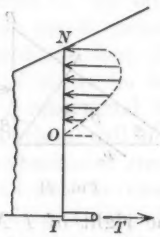

FIG. 25.

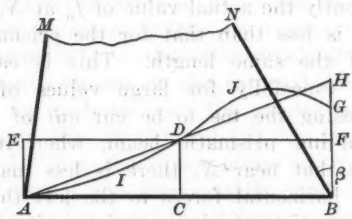

FIG. 26.

The variation of this stress is shown in Fig. 26, which may be taken as typical of the results of the various experiments. In this figure, $A\ B$ is a horizontal section of the dam, $A\ B\ N\ M$, near its base, the angle, β, being 40° 55′ for the plasticine dam and 32° for the straight portion of the rubber dam. The resultant on the section was supposed to cut it, $\frac{1}{3}\ A\ B$ from B, so that the vertical ordinates from AB to a straight line, $A\ H$, represent the stresses in question, according to the usual theory. Also, if C is the mid-point of $A\ B$, the vertical ordinates from $A\ B$ to $E\ F$ represent the uniform compression due to the supposed vertical load at C. The ordinates from $D\ F$ to $D\ H$ and from $D\ E$ to $D\ A$ represent the stresses due to the bending moment, all according to the ordinary theory. By experiment, the vertical unit stress on $A\ B$, at any point of it, is given by the vertical ordinate there, from $A\ B$ to the curved line, $A\ I\ D\ J\ G$. The variation of stress due to a central load at C is unknown, but it is certainly not uniform, and the stress is a little less than $B\ F$ at B, and probably a little greater than $C\ D$ at C, the variation being given by the ordinates from $A\ B$ to a slightly curved line between the extreme points, and not by $E\ D\ F$. The actual unit stresses corre-

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII, Session 1907–08, Part II, see Pl. 3, Fig. 4, and Pl. 5, Figs. 19–21.

sponding to the bending moment will be represented by the vertical ordinates between this slightly curved line and *A I D J G*. This (for the part, *C B*, of the section) would give about the variation of stress shown in Fig. 25. The unit stress, corresponding to the bending moment, that particularly interests us, is that at *B*, Fig. 26, which is represented by a vertical line from *G* to a point slightly below *F*. This stress will be smaller than *F H*, and, similarly, we should conclude for the toe, Fig. 22 (1), that f_0 as computed is too large (at least for $\beta = 32°$ to $41°$), though the excess over the true value is negligible near the truncated end of the toe and increases as the stem is approached where it is comparatively large. Mr. Cain.

No quantitative results can well be given, but a glance at the diagrams, relating to the experiments on the dams referred to, will show an excess in the total vertical unit stress on a horizontal plane, say one-fifth of the height of the dam above the foundation, of more than 25%, the amount increasing very materially as the foundation is neared. From the relation between this stress and the part of it due to flexure, we must infer a large proportion of the same excess in the computed over the real value of the stress due to direct bending. A similar result then would follow for the toe in question.

From all that precedes, both as to facts and theory, it follows, for the toe, Fig. 22 (1), that f_0, as usually computed, is in excess of the true value, the amount being small for small values of β and increasing with β, slowly at first and more rapidly when β is large, the excess being enormous when β approaches 90 degrees. Further, it would appear that this excess should be very small when the section, *I N*, is taken near the truncated end of the toe, and that it should increase as the vertical section is taken nearer its junction with the stem of the retaining wall, where it is a maximum.

A comparison will now be made between the results obtained in computing the principal stress at *N*, (1) by the formula previously given,

$$p_0 = f_0 \sec.^2 \beta = \frac{c}{k_0 j_0} \sec.^2 \beta$$

and (2) by use of Equation 15 of the writer's paper,*

$$f_c = \frac{2M}{kj\, bd^2 \cos.^2 \beta} = \frac{c}{kj} \sec.^2 \beta,$$

where, $c = \frac{2M}{bd^2}$, Fig. 22 (2), showing the assumed distribution of stresses along the vertical section.

On dividing the first equation by the second, we have,

$$\frac{p_0}{f_c} = \frac{kj}{k_0 j_0}$$

* *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 756.

Mr. Cain.

where k, j, refer to System (2) of stresses, the values being taken from the full lines of the diagram, Fig. 6, of the writer's paper,* for the assumed value of β. The values of k_0, j_0, may be found on the same diagram from the line corresponding to $\beta = 0$.

The results are given in Table 3 for various values of β and $p = \frac{A}{b\,d}$.

TABLE 3.—STEEL PERCENTAGE, 100 p.

$100\,p =$	0.2	0.6	1.0	2.0
	$\frac{p_0}{f_c}$	$\frac{p_0}{f_c}$	$\frac{p_0}{f_c}$	$\frac{p_0}{f_c}$
$\beta = 10°$	1.02	1.02	1.01	1.00
20°	1.05	1.05	1.04	1.02
30°	1.13	1.11	1.09	1.06
40°	1.24	1.20	1.17	1.12

In Fig. 22, $d = I\,N$, b = constant width of section
In Fig. 22 (1), $k_0\,d = N\,O$, $j_0\,d = D\,I$.
In Fig. 22 (2), $k\,d = N\,O$, $j\,d = D\,I$.

Recalling that p_0 is always in excess of the true value, the excess appreciably increasing with β, the values of f_c, corresponding to System 2 of Fig. 22, are seen to give consistent results and in the right direction. The regularity of the changes in the ratio is noticeable, and the near approach to unity for $\beta = 10$ to 20 degrees. The excess of p_0 over f_c, which varies from 0 to an extreme of 24% for $100\,p = 0.2$, $\beta = 40°$, is what might have been expected from the diagrams relating to the experiments. Also, since the computed value of p_0 for the toe, is in excess (much more than 25%) near or at its junction with the stem for $\beta = 32°$ or $\beta = 41°$, reasoning from the results of the experiments on dams, it is seen from Table 3 that f_c for $\beta = 32°$ or $\beta = 41°$, is in excess of the true value, and, presumably, f_c is in excess for any value of β considered.

It is impossible to draw certain conclusions when experiments in great variety are lacking, but all the results, theoretical and experimental, given thus far tend to support the approximate formula for f_c, as a good practical formula within the limits $\beta = 0$ to $\beta = 45°$, and on the side of safety. Further, the value of f_c, as just computed, is much nearer the truth than the value of $p_0 = f_0 \sec.^2 \beta$.

It has been suggested that perhaps $f_0 \sec. \beta$ would be preferable to use, as a semi-empirical formula, in place of $f_0 \sec.^2 \beta$, which gives results too large. Calling $p_0' = f_0 \sec. \beta$, the ratio $\frac{p_0'}{f_c}$ was made out for different steel percentages and values of β, as given in Table 4.

* *Loc. cit.*, p. 755.

TABLE 4.—STEEL PERCENTAGE, 100 p.

Mr. Cain.

$100\,p =$	0.2	0.6	1.0	2.0
	$\frac{p'_0}{f_c}$	$\frac{p'_0}{f_c}$	$\frac{p'_0}{f_c}$	$\frac{p'_0}{f_c}$
$\beta = 10°$	1.01	1.01	1.00	0.99
20°	0.99	0.99	0.98	0.96
30°	0.98	0.97	0.95	0.92
40°	0.95	0.92	0.90	0.86

As p_0' is generally less than f_c, until more decisive experimental evidence is forthcoming, it seems unwise to use the smaller value.

Although the previous investigation shows that the value, p_0, is always in excess, and that f_c is nearer the true value, the question at once occurs: why not use, for such an uncertain quantity as concrete, the larger value?

By reference to Table 3, it is seen that p_0 exceeds f_c by from 1 to 5% only, for $10° < \beta < 20°$ and by from 6 to 24% for $30° < \beta < 40°$, for the various steel percentages. The average excess is small; besides, the junction of toe and stem is a recognized point of weakness in concrete construction, so that a decided excess value seems desirable. Further, the method of computation of p_0 is simple and more generally understood than the method by which f_c is computed, which introduces the novel hypothesis of parallel stresses. If this method is adopted in the computation of f_0, Fig. 22 (1), the values of k_0 and j_0 can be found from usual diagrams pertaining to prismatic beams, the principal stress in the concrete computed from the formula, $p_0 = f_0 \sec.^2 \beta$, and the stress in the steel (which is usually the determining factor) found as usual. If p_0 is assigned a limit of say, 650 lb. per sq. in., then $f_0 = 650 \times \cos.^2 \beta$; with this value and the maximum unit stress allowed in the steel, the usual French diagram can be consulted. The serious drawback to the use of this method is that f_0 is known to be in excess, and that the state of stress shown in Fig. 22 (1), cannot be justified. We have seen, though, that the state of stress shown in Fig. 22 (2) is on a more satisfactory basis, in that it introduces β and f_c from the start, and that it may be near the true state, any variation being most marked near N. At any rate, it is a good working hypothesis, consistent with the few experiments available, and to be tested by future more direct experiments. The formulas corresponding to the hypotheses have been developed by rigorous methods, and the resulting values of f_c agree fairly well with the results of the experiments quoted. It seems to be common practice (which Mr. Janni endorses,

Mr. Cain.

when "β is not large") to use f_0 as the "maximum compressive stress" in the concrete, in place of either p_0 or f_c. It would appear from the foregoing investigation, that such practice may be considerably on the danger side, and should be condemned—certainly until more decisive results can be reached from future experiments.

The previous discussion deals with the case where $\beta > 0$ and $\beta_1 = 0$. For the case of the heels and counterforts of retaining walls, $\beta = 0$, and, generally, some of the steel bars are not at right angles to the section, $I\ N$. For this case, all the general formulas of the writer's paper hold on putting $\beta = 0$. This is a much simpler case than the former, since the only hypothesis introduced is that plane sections remain such after bending.

In the writer's first draft of his paper, this case was considered by itself, and, following it, the case where $\beta > 0$, which introduced a second hypothesis as to parallel stresses. Both cases were then combined into one to save space in the final writing. It is regretted now that the two cases were not considered separately, as then the merits or demerits of each could have been more easily seen or discussed.

Taking up again Mr. Janni's further comments, it may be observed that his Fig. 17 shows a buttressed wall, which is not the case of the counterforted wall investigated by the writer. In the latter, the earth is to the right of the face wall, the counterfort being buried in it. The force, F, of Fig. 17, thus acts to the left. In practice, too, the friction forces are usually neglected, for simplicity. The base of the counterfort is connected to the foundation slab (which is loaded with earth) by steel rods, vertical and inclined, so that the counterfort can be regarded as a beam fixed at the ends or at its junction with the base slab. It is true that it is a very short beam, so that the effect of shear is very large; still, a bending moment has to be accounted for, and beam action is thus induced. The theory of such beam action enables one to compute the stresses in the rods, as was illustrated in connection with Fig. 3.*

With regard to the toe-beam, Fig. 18, if the friction is included, the "principal stress" at P' is, of course, inclined to the horizontal; but the writer had in mind the "bending stress", as explained in the foregoing, which was taken as acting parallel to $L\ I$, according to the original assumption. Mr. Janni is right in his remark about the modulus, E, not exactly applying, as before remarked. It was considered, however, that in an approximate computation, the Poisson ratio consideration could be ignored, particularly as in concrete this ratio is very small. In all approximate computations, one or more assumptions, not exactly true, are usually made, it being considered that the degree of accuracy in the final computations is the final test, and, from what has preceded (see Table 4) the computations for f_c

* *Loc. cit.*, p. 751.

stand the test for practical accuracy remarkably well. The ordinary modulus could evidently be used near the surface, where the larger stresses with the larger arms are most effective in resisting the bending couple, so that the error should not be large in using a constant modulus throughout. Mr. Cain.

As to shear, let Fig. 27 represent an infinitesimal rhombic prism at the neutral axis, two faces being parallel to the neutral surface, OO', and the other faces being vertical. The stress on the two vertical faces shown is a pure shear, s. As there is generally a vertical component on all planes parallel to OO' to the compressed surface, the possibility of such a component must be recognized at the neutral surface. Then, if we resolve r, the resultant unit stress on $O\,O'$, into a vertical component, t, and one acting parallel to $O\,O'$, it follows that the latter is equal to s, as is shown by taking moments of the forces shown, say about O. By reference to Fig. 8,* it is seen that s, this component of r, is given by Equation 17, and is thus identical in value with v of the formula. The unit shear, s, on a vertical plane is likewise equal to the unit shear on a horizontal plane at O, from the well-known theorem. In the demonstration, OO' was assumed to be parallel to the upper surface, which is not strictly true; in addition, V should have the meaning given later, where shear is thoroughly discussed. It can be easily shown, by a slight modification of usual methods, that the unit shear component, s (as just defined), on a plane parallel to OO' (assumed to be parallel to the surface) and at a vertical distance, y, above it, is given by the formula,

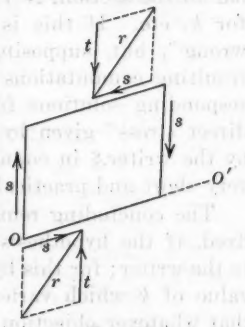

FIG. 27.

$$s = \frac{V}{b\,(k\,d_1)^2 \,.\, D\,G}\,[(k\,d_1)^2 - y_1{}^2]^2.$$

Thus, this component, s, varies according to the parabolic law, and is zero when $y_1 = k\,d_1$ or at the surface, as we know to be true from the elementary considerations given in connection with Fig. 1.†

This component, s, is thus exactly the shear on a horizontal or vertical plane at O, and "above the neutral surface, it decreases, by the usual parabolic law, to zero at N." It is not the shear on a horizontal or vertical plane between O and N. That will be given later.

It will be observed, at the point, O, that if r, Fig. 27, is resolved into components perpendicular and parallel to OO', the latter—the full shear on OO'—may be greater than s. The vertical component was

* *Loc. cit.*, p. 758.
† *Loc. cit.*, p. 746.

Mr. Cain. overlooked in the writer's first analysis. The decomposition indicates that the true shear on OO' may be greater than s.

Mr. Janni again introduces Fig. 10,* in which it seems that he intends to leave the part of the beam to the left of $I\ N$ unchanged, as MN shifts to the different positions shown by the dotted lines. As β approaches 90°, the value of f_c, given by him, becomes smaller and smaller for a constant M, and at $\beta = 90°$, $f_c = 0$, which is characterized as absurd. Messrs Slocum and Hancock† give a complete solution of this case. These authors conclude that "if a piece is bent exactly at right angles on itself, the slightest bending strain must produce incipient rupture"; also, that "the neutral axis passes through the vertex of the angle" (N in Fig. 10). This seems to dispose of Mr. Janni's "absurd conclusion."

As to the solution proposed by Mr. Janni in connection with Fig. 19, no objection can be urged, provided the inclination of the reinforcing bar to the section, $N\ I$, is properly included in deducing the formulas for k, etc. If this is not done, then the solution would be "flatly wrong"; but, supposing a correct solution to have been made, the resulting computations would be long and wearisome, as note the corresponding solutions for a prismatic beam, subjected to "flexure and direct stress" given by Turneaure and Maurer.‡ The solution given by the writer,§ in connection with the diagram for finding k and j, is very short and practical.

The concluding remarks of Mr. Janni about the neutral axis being fixed, if the hypothesis of parallel stresses is adopted, is inexplicable to the writer; for this hypothesis leads by rigorous mechanical laws to a value of k which varies with β, β_1, etc. It may be added, likewise, that whatever objection applies to the determination of k, with regard to the state of stress shown in Fig. 22 (2), would seem to apply equally to the state of stress shown in Fig. 22 (1), when β was not zero. The exact determination of O is doubtless a very complicated problem, which awaits a solution. The writer's only aim was to get an approximate result leading to safe formulas.

The writer has studied more carefully the subject of shear, since the publication of his paper, and is glad of this opportunity to state his agreement, in part, with Mr. Nishkian in his contention that the vertical component of the stress in the inclined rod should be deducted from the vertical load to get the shear in the concrete of the heel, Fig. 12.|| Thus, to take a more general case, consider the toe, Fig. 28, subjected to the vertical load, Q. The stress, C, inclined at the angle, β,

* *Loc. cit.*, p. 766.

† "Text-book on the Strength of Materials," Art. 127.

‡ "Principles of Reinforced Concrete," Arts. 80–85.

§ *Transactions*, Am. Soc. C. E., Vol. LXXVII, p. 756.

|| *Loc. cit.*, p. 768.

the tension in the rod at I inclined at the angle, β_0, to the horizontal, and the shear, V, in the section, $N\ I$, to be carried by the concrete, in addition to the vertical component of C already included. V is thus the shear in the section still to be accounted for after the vertical components of C and T have both been considered. For equilibrium, we must have, Mr. Cain.

$$V = Q - C \text{ sin. } \beta - T \text{ sin. } \beta_0.$$

This portion, $L\ M\ N\ I$, of the beam acts on the part of the beam to the right of the section, $N\ I$, with forces exactly equal and opposed to C, T, and V.

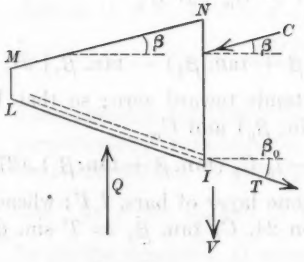

FIG. 28.

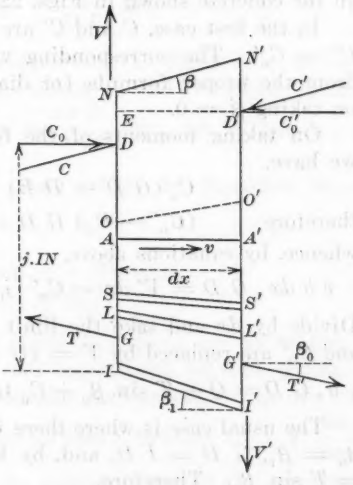

FIG. 29.

When the steel is horizontal, $\beta_0 = 0$ and $V = Q - C$ sin. β. This refers to the case shown in Fig. 22 (2). For the case shown in Fig. 22 (1), C is horizontal and $V = Q$. When T, Fig. 28, acts upward, the last term in the first formula changes sign. In the first investigation of shear, C' was assumed to act in the same line as C, which is only approximately true. To make an exact analysis, consider Fig. 29, representing a portion of the beam between the two vertical sections, $I\ N$ and $I'\ N'$, dx apart and subjected to the forces, V, V', C, and C' (the horizontal components of which are C_0, C_0'), T, the resultant of the tensions in the bars, $I\ I'$, $L\ L'$, $S\ S'$, acting at G and inclined at the angle, β_0, to the horizontal and the corresponding resultant, T', at G', supposed to act in the line of T, but opposite in direction. The constant width of the cross-sections will be called b, and the unit shear

Mr. Cain.

on a horizontal plane, $A\ A'$, just below the neutral surface, v. We have,

$$I'\ D' - I\ D = j\ (I'\ N' - I\ N) = j\ dx\ (\tan.\ \beta + \tan.\ \beta_1)$$
$$D\ E = I\ E - I\ D = I'\ D' - dx \tan.\ \beta_1 - I\ D = j\ dx\ (\tan.\ \beta + \tan.\ \beta_1) - dx \tan.\ \beta_1.$$

Now, whatever the inclinations assumed of C and C', we have

$$C_0 = T \cos.\ \beta_0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$
$$C_0' - C_0 = v\ b\ dx \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

the latter equation resulting from placing the sum of the horizontal components of the forces acting on $A\ A'\ N'\ N$ equal to zero. Two cases will be considered, corresponding to the dispositions of stress in the concrete shown in Figs. 22 (1) and (2).

In the first case, C and C' are taken as horizontal; whence $C = C_0$, $C' = C_0'$. The corresponding value of j (call it j_0) can be derived from the proper formula (or diagram, for one layer of rods at $I\ I'$) on taking $\beta = 0$.

On taking moments of the forces acting on $I\ I'\ N'\ N$ about G, we have,

$$C_0'(G\ D + D\ E) - C_0\ .\ G\ D = V'\ dx \quad \ldots\ldots\ldots\ldots (26)$$

therefore $$(C_0' - C_0)\ G\ D = V'\ dx - C_0'\ .\ D\ E;$$

whence, by equations above,

$$v\ b\ dx\ .\ G\ D = V'\ dx - C_0'\ [j_0\ (\tan.\ \beta + \tan.\ \beta_1) - \tan.\ \beta_1]\ dx.$$

Divide by dx and take the limit as dx tends toward zero; so that V' and C_0' are replaced by $V = (Q - T \sin.\ \beta_0)$ and C_0.

$$v\ b\ .\ G\ D = Q - T \sin.\ \beta_0 + C_0 \tan.\ \beta_1 - j_0\ C_0\ (\tan.\ \beta + \tan.\ \beta_1)\ . \quad (27)$$

The usual case is where there is only one layer of bars, $I\ I'$; whence $\beta_0 = \beta_1$, $G\ D = I\ D$, and, by Equation 24, $C_0 \tan.\ \beta_1 = T \sin.\ \beta_1 = T \sin.\ \beta_0$. Therefore,

$$v\ b\ .\ G\ D = Q - j_0\ (C_0 \tan.\ \beta + T \sin.\ \beta_1) \quad \ldots\ldots\ldots (28)$$

where $G\ D = j_0\ .\ I\ N$.

In the second case, C and C' will be assumed to act parallel to $N\ N'$. Therefore, $C_0 = C \cos.\ \beta$, $C_0' = C' \cos.\ \beta$, and j is to be found as usual, for the given value of β. The right member of Equation 26 is now to be increased by $C' \sin.\ \beta\ .\ dx$; whence, proceeding as before, and substituting, $V = Q - T \sin.\ \beta_0 - C \sin.\ \beta$, as just explained, we have,

$$v\ b\ .\ G\ D = Q - T \sin.\ \beta_0 + C_0 \tan.\ \beta_1 - j\ C_0\ (\tan.\ \beta + \beta_1)\ . \quad (29)$$

where $C_0 = C \cos.\ \beta$. For one layer of bars $I\ I'$, $\beta_0 = \beta_1$, $G\ D = I\ D$, $C_0 \tan.\ \beta_1 = T \sin.\ \beta_0$. Therefore

$$v\ b\ .\ G\ D = Q - j\ (C \sin.\ \beta + T \sin.\ \beta_1) \quad \ldots\ldots\ldots (30)$$

where $G\ D = j\ .\ I\ N$.

In Equations 27 to 30, on dividing by $b \,.\, G\, D$, we find the shear, v. Note in the right member of Equation 30, that in place of subtracting the sum of the vertical components of C and T from Q, that only j times this amount is subtracted.* Mr. Cain.

The bond stress for the general case of many layers of bars, Fig. 29, is easily found. Using the previous notation,† and since the shear on the horizontal plane, $A\ A'$, equals the sum of the horizontal components of the bond stresses in the bars, Fig. 27,

$$b\, v\, dx = u_1\, I\, I' \cos.\, \beta_1\, \Sigma o_1 + u_2\, LL' \cos.\, \beta_2\, \Sigma o_2 + \ldots$$
$$= dx\,(u_1\, \Sigma o_1 + u_2\, \Sigma o_2 + \ldots)$$

$$\text{Therefore, } b\, v = u_1 \left[\Sigma o_1 + \frac{O\ L}{O\ I}\, \Sigma o_2 + \frac{O\ S}{O\ I}\, \Sigma o_3 + \ldots \right] \ldots\ldots\ldots (31)$$

For any one of the cases corresponding to Equations 27 to 30, substitute the value of $b\ v$ corresponding, in the foregoing equation, whence u_1, and, subsequently, $u_2 = u_1 \dfrac{O\ L}{O\ I}$, etc., can be found. For only one layer of bars, $u_1 = \dfrac{b\ v}{\Sigma o_1}$, and using, say, Equation 30, also placing $D\ G = D\ I = j \,.\, I\ N$,

$$u_1 = \frac{Q - j\,(C \sin.\, \beta + T \sin.\, \beta_1)}{j \,.\, I\, N\, \Sigma o_1} \ldots\ldots\ldots\ldots (32)$$

The formulas for shear and bond stress just given are to replace the corresponding formulas for shear and bond stress hitherto given. In the applications, it may prove desirable to express C_0 in the "first case" by $T \cos.\, \beta_0$, and in the "second case" to place $C = T \dfrac{\cos.\, \beta_0}{\cos.\, \beta}$. In all the formulas, Q represents the algebraic sum of the reaction (if any) and the loads left of the section $I\ N$. Also, if T' is directed to the right and upward, sin. β_0 is changed to $(-$ sin. $\beta_0)$. Similarly, change β_1 to $(-\ \beta_1)$ if $I\ I'$ lies above the horizontal through I, with a consequent change of sign of sin. β_1 and tan. β_1.

It will be observed that, in consequence of the term subtracted from Q being often large, the values of v and u are small as compared

* In Mörsch's "Concrete-Steel Construction" (Goodrich's translation), p. 190, similar results, for some of the simplest cases, are found by a very neat method involving the calculus. This method can easily be extended to other cases, but it is perhaps not so obvious as the above. The moment, M, of the external forces about either G or D is constant; hence, for one layer of rods, $I\ I'$, with G at I, $M = C_0 \,.\, j_0\, I\, N$ in Equation 28 $= C$ cos. $\beta \,.\, j\, I\, N$ in Equation 30; therefore $j_0\ C_0$ tan. β in Equation 28 $= j\ C$ sin. β in Equation 30. Similarly, if T_0 is put for T in Equation 28 to distinguish it from the T in Equation 30, $T_0\, j_0\, I\, N$ in Equation 28 $= T j\ I\, N$ in Equation 30; therefore $T_0\, j_0$ sin. β_1 in Equation 28 $= T\, j$ sin. β_1 in Equation 30. Whence the right members of Equations 28 and 30 are equal in value; so that the values of v derived from Equations 28 and 30 are in the ratio of the $G\ D = j \,.\, I\, N$ of Equation 30 to the $G\ D = j_0 \,.\, I\, N$ of Equation 28, or of j to j_0. The values j and j_0 differ by only a small percentage.

† *Loc. cit.*, p. 760.

Mr. Cain.

with results obtained for prismatic beams where $\beta = 0$, $\beta_1 = 0$. Hence it will rarely be necessary to use the formulas above in their entirety, since a rough estimation of the subtractive term will generally suffice to indicate safe limits.

It has been remarked, in connection with Fig. 27, that the unit shear at O, on a plane inclined to the horizontal, may be greater than the shear on the horizontal plane. The difference will usually be small. The unit shear, q, on a horizontal plane at the distance, y_1, above O in the case of the toe, Fig. 22 (1), for the state of stress shown in that figure, can be found by a method similar to that used for prismatic beams, only the rise of N' above N and of O' above O, Fig. 29, must be considered in the limits of the integrations, etc. The results are to be written only to first order infinitesimals, but even then, the work is long, so that only the final result will be given. As before, b = constant breadth and d = depth, $N\ I$, Fig. 22 (1), M = moment of external forces about I, and k_0, j_0, refer to the state of stress shown in the figure. The value of q is given by the following equation,

$$q\ (k_0^2\ j_0\ b\ d^3) =$$

$$k_0^2\ d\ (Q\ d - M \tan.\ \beta) + [2\ (1 - k_0)\ M \tan.\ \beta]\ y_1$$

$$+ \left[\frac{3\ M \tan.\ \beta}{d} - Q\right] y_1^2 \ldots\ldots\ldots\ldots\ldots\ldots (33)$$

The unit shear at O is found by putting $y_1 = 0$ and substituting $C_0\ j_0\ d$ for M,

$$q\ (\text{at } O) = \frac{Q - j_0\ C_0 \tan.\ \beta}{b\ .\ j_0\ d},$$

as found in another manner above. At N, the shear is found by putting $y_1 = k_0\ d$. Therefore,

$$q\ (\text{at } N) = \frac{2\ M \tan.\ \beta}{k_0\ j_0\ b\ d^2} = f_0 \tan.\ \beta,$$

as can be proved independently. Here, f_0 indicates the direct bending stress at N, Fig. 22 (1).

Another check is afforded by taking $\beta = 0$, whence,

$$q = \frac{Q\ (k_0^2\ d^2 - y_1^2)}{k_0^2\ j_0\ b\ d^3}$$

which is very easily proved independently.

Reasons have been given for the computed value of f_0 being in excess, the state of horizontal stress on the vertical plane, $I\ N$, being nearer that shown in Fig. 25 than the one given in Fig. 22 (1); hence q at $N < f_0 \tan.\ \beta$, and, similarly, the variation in q is not exactly that given by the equation, as y_1 increases from zero to $O\ N$. How-

ever, accepting it as showing roughly the variation in q, it is seen that Equation 33 can be written in the form, Mr. Cain.

$$q = l + m\,y_1 + n\,y_1^2,$$

where q and y_1 are the only variables. When $n = 0$, this is the equation of a straight line. When n is not zero, it may be positive or negative, and the equation is that of a parabola, the axis of which is horizontal, and the vertex is at the point, the abscissa of which (parallel to axis of q) is $\left(l - \frac{m^2}{4\,n}\right)$ and the ordinate (parallel to axis of y_1) is $\left(-\frac{m}{n}\right)$.

Figs. 30 and 31 show the loci for $n > 0$, $n < 0$, respectively, for assumed values, the value of q at $y_1 = O\,N$, being f_0 tan. β in both cases. In Fig. 30, q increases with y_1 from O to N; in Fig. 31, q decreases with y_1 above the vertex. Of course, only the portions of the curves from $y_1 = 0$ to $y_1 = O\,N$ pertain to the problem. If the load, Q, acts a units to the left of $I\,N$, Fig. 22 (1), we have, $M = Q\,a$, hence,

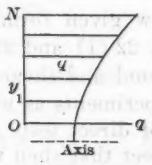

FIG. 30.

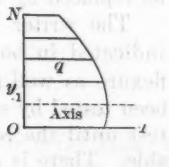

FIG. 31.

$$l = \frac{Q\,(d - a \text{ tan. } \beta)}{j_0\,b\,d^2}$$

is always positive, since $d > a$ tan. β. In fact, when $y_1 = 0$, $q = l$, or the shear at the origin acts to the right, so that the locus, whether a parabola or a straight line, cuts the axis of q to the right of O. It is evident from the general equation above that m is always positive. Also, since

$$n = \frac{Q}{k_0^2\,j_0\,b\,d^3}\left(\frac{3\,a \text{ tan. } \beta}{d} - 1\right).$$

it is evident that,

$$n > 0, = 0, < 0,$$

according as,

$$a \text{ tan. } \beta > \frac{d}{3}, = \frac{d}{3}, < \frac{d}{3},$$

corresponding, respectively, to a long toe, a medium toe, or a very short toe. When n is positive, the abscissa of the vertex may be positive, as shown in Fig. 30, or it may be negative. When n approaches zero, the vertex recedes indefinitely to the left and downward, and the locus approaches the straight line, $q = l + m\,y_1$, where m and l are always positive.

Mr. Cain.

Similarly, when n is negative, Fig. 31, although the vertex of the parabola is always in the first quadrant, yet as n tends toward zero, it recedes indefinitely from the origin, and the shear increases in going from O to N, and the locus approaches again the straight line, $q = l + m\, y_1$.

The foregoing general formula only gives the unit shear, q, on a horizontal (or vertical) plane at the distance, y_1, above O. At this point, in addition to these shears, there is a horizontal pressure, f, on a vertical plane and a vertical pressure on a horizontal plane. The latter is unknown, except at the surface, $M\ N$, where it is $f_0 \tan.^2 \beta$, as can easily be proved by aid of an infinitesimal wedge like $A\ M\ B$, Fig. 23.

If the state of stress indicated by Fig. 22 (2) is assumed, the same general formula, as given above, is derived, except that k_0, j_0, are to be replaced by k, j.

The writer has now given formulas for the two states of stress indicated in both Fig. 22 (1) and 22 (2), referring to stresses due to flexure as well as to bond and shear stresses, and certain results have been tested by such experiments as were available. The case must now rest until the results of direct tests on wedge-shaped beams are available. There is a prospect that such tests will be made at several institutions within the next year.

GROUTED CUT-OFF FOR THE ESTACADA DAM.

Discussion.*

By Harold A. Rands, Assoc. M. Am. Soc. C. E.†

Mr. Rands.

Harold A. Rands,‡ Assoc. M. Am. Soc. C. E. (by letter).—This paper has brought forth expressions and observations from members of the Profession who have had experience in grouting, and, although it was hoped that others would be heard from, it is believed that, in a general way, the discussions cover the knowledge concerning this subject at the present time. In addition to the structures cited in the paper and the discussion, in the construction of which grouting has been resorted to, mention may be made of the Hale's Bar Dam, in Tennessee, the Houlter Dam, in Montana, the Kananaskis Dam, in Alberta, and the Municipal Dam of the City of Seattle.

Possibly what might be the most interesting and instructive case of all is that of a high earth dam, the fill for which was commenced without due regard for obtaining a tight cut-off. After the dam was completed, and the pond filled, the leakage assumed serious proportions, and the back portion of the dam itself began to slough away. Holes were put down at various points through the dam and into the underlying material, and grouting was resorted to. It is reported that a total of 30 000 bbl. of cement, in the form of grout, was poured or pumped into this dam, though, unfortunately for the Profession, the "soft pedal" was put on the engineers in charge of the work, and the facts were never published.

This dam is mentioned here as showing the importance of careful attention to the blind cut-off of an earth dam. In contrast with the lack of consideration in this case, attention is called to the Lahontan

* Continued from August, 1914, *Proceedings*.
† Author's closure.
‡ Oregon City, Ore.

Mr. Rands.

Dam, in Nevada, which is also of earth, and beneath which the engineers of the Reclamation Service specified a concrete cut-off, 30 ft. deep, with a grouted cut-off going down an additional 30 ft., or 60 ft. in all.

Considering the contributions from the engineers connected with the Estacada Dam, we have first the discussion by Mr. Rippey. In the earlier paragraphs of his discussion, Mr. Rippey expresses fear lest the writer's views be given too much weight, and sums up the reasons for his somewhat extended discussion, in the following:

"In order, therefore, that the results obtained at Estacada, and the conclusions drawn therefrom by Mr. Rands, may be properly appraised by others interested in the treatment of deficient foundations, it is proper to outline, as briefly as possible, sufficient of the history of that project to indicate the unfavorable character of the governing conditions under which the work was executed."

Mr. Rippey then proceeds to attribute the comparatively poor showing made by the grouting at Estacada to "lack of co-operation" on the part of the local organization of the company owning the dam.

The writer went to considerable pains to avoid mentioning the "Chapters of Grief" which unfortunately marked the construction of the Estacada Dam, believing that the Profession at large is only concerned in such affairs when they affect results. In this particular case, it was his belief that the great amount of detailed information, together with the tables and curves submitted, constituted fairly acceptable evidence as to the care, and the regard to detail, with which the grouting was carried out.

However, since the publication of Mr. Rippey's part in the discussion, the author has received a letter from one of the foremost hydraulic engineers in the United States, wherein is expressed the opinion that grouting, to be successful, must be done with close attention and care in every detail. As this sentiment, in part, may be the result of the reading of Mr. Rippey's discussion, and possibly is shared by others, it may be proper to cover in a paragraph the history of the Estacada Dam.

During the preliminary investigation and the first three months of the construction period, the work was completely under the direction of the local organization, with Messrs. Sellers and Rippey acting as Consulting Engineers; during this period no grouting was done. During the next five months—or what may be called the middle portion of the construction period—the work was under the direction of the Sellers and Rippey organization, with Mr. William H. Cushman in charge as Resident Engineer; it was during this time that the grouting was commenced. During the remainder of the construction, the work was under the direction of the local organization, with Mr. Frank R. Fisher in charge as Resident Engineer, and with Messrs. Sellers and Rippey continuing as Consulting Engineers. The construction force, it should

be said, was under the direction of the contractors, the Puget Sound Bridge and Dredging Company, except as to the grouting, which was directed at all times and as to all details by the Resident Engineer. Mr. Rands.

The change in the middle of the work, which came as a result of conflict in organizations in a job literally loaded down with organizations, and not from anything which in any way reflects on either the integrity or engineering ability of any one, in place of affecting the grouting injuriously, really amounted to giving it a second trial, with every added care and refinement of detail which it was possible to devise. In fact, so poor was the showing being made by the grouting, both at Estacada and at the site of the proposed 150-ft. dam, at the time of the second change of management, that it is probable it would have been discontinued altogether, but for this change. Both Mr. Cushman and Mr. Fisher, it may be added, have reputations for thoroughness and attention to detail.

As to the writer's personal opinions and theories, though they might be subject to liberal discount, were they based wholly on the somewhat negative results at Estacada, they may be entitled to some additional consideration by reason of their having been tried out on another grouting job which proved more successful.

Soon after the completion of the Estacada Dam, the writer was engaged by E. G. Hopson, M. Am. Soc. C. E., Supervising Engineer of the Reclamation Service, to go to Nevada, and take charge, under D. W. Cole and F. H. Tillinghast, Members, Am. Soc. C. E., Project Engineer and Resident Engineer, respectively, of the grouting of the Lahontan Dam. This work has been described fully by Mr. Cole in articles appearing in the engineering papers, and it is interesting to contrast the results obtained in the poorer or left-channel section at Estacada with those in the poorer or second section at Lahontan.

At Estacada, the final tests showed an average leakage, at full depth, of 36 gal. per min., or 75% of the leakage of the primary holes at the same point; at Lahontan, it was only 6 gal. per min., or 9% of the leakage of the primary holes. At Estacada, a very small head of water against the coffer-dam produced, even in the final holes, a very heavy back-flow; at Lahontan, all back-flow ceased before the final holes were put down. At Estacada, communication between the seventeen final proving holes was so free that a pressure slightly exceeding the head to be produced by the dam applied to one of them caused water to flow from all the others; at Lahontan, the grouting of all the holes as soon as drilled prevented the observance of anything directly comparable to this, yet, at times, a second hole would be down to nearly full depth only 12 ft. from a hole being tested, and the fact that no water was forced from the former hole shows that there was no communication, as at Estacada.

Mr. Rands.

At Lahontan, it may be stated, there was evidence of a change in the structure of the underlying material, in that in the earlier holes put down there was much trouble from caving, and binding of the drills in the holes, in some cases causing the loss of an entire shift, and even of the bits, in getting the rods up and the caved material re-drilled; in the drilling of the final holes, no such trouble was experienced, the whole number being put down without a drill sticking or a single cave-in.

As the writer takes little blame to himself for the relatively poor showing at Estacada, so does he take little credit to himself for the relatively good showing made at Lahontan. Though experience taught him much during the grouting of the 34 000 ft. of drilling at Estacada, there was not enough difference between the methods used on that work and at Lahontan to account for the difference in results. The real reason, in the writer's opinion, is one of geology, and therein, and not in the lack of sympathetic co-operation, lies the vindication of Mr. Rippey.

Referring again to the paper by Mr. Schreiber, read before the Western Cement Users Association, and wherein is set forth what Mr. Rippey hoped for in recommending grouting for the Estacada Dam (page 10*), it will be noted that the recommendation concludes with the following:

"It [the sufficiency of the grouting] must be susceptible of demonstration by actual test before the superstructures should be started."

At Estacada it was tried with indifferent success, due to the geological formation; at Lahontan it was tried with positive success, again due to the geological formation.

It was with no spirit of irony that the writer, in the paper, stated that the credit for evolving the grouting programme for the Estacada Dam belonged to Mr. Rippey, and it is with no spirit of irony that it is repeated. He not only proposed the programme for this work, but what is more, he gave the Profession the only safe rule to be followed in cases where grouting is to be resorted to in lieu of the usual concrete cut-off.

The proposal of Mr. Hulse to resort to slow sedimentation in lieu of the more rapid pressure grouting is a real addition to the subject, though, in the writer's opinion, this should not be resorted to until the latter had failed to produce results. The writer still believes that to continue almost indefinitely the pouring of thin cement grout into a hole is, in a great measure, to waste the cement, for, to quote Mr. White:

"It may run a long way from the part to be grouted, and on excavating this part, very little of it will be found. No one knows where it went—all that is known is that one has paid for it."

* *Proceedings*, Am. Soc. C. E., for January, 1914.

Mr. Hulse does not believe that it is safe to blast a trench in the material on which it is proposed to erect a great dam, and expresses himself as follows: Mr. Randa.

"If it [the trenching] is done by blasting, * * * there is great danger of doing almost irreparable damage to the surrounding material, and this is exactly what happened in the left channel at Estacada, where the breccia adjoining the heel-trench was shaken and cracked in all directions by the blasting."

The writer believes that this statement is far too strong, and may leave the impression that the Estacada Dam, because of the blasting for the cut-off, is standing on unsafe and insecure foundations.

It is admitted that the blasting for the cut-off trench was, in the beginning, ignorantly done; and, to support this statement, it is only necessary to say that twenty-one vertical surface holes were loaded and fired at one time. The result of this was to loosen up a large quantity of material which had to be replaced with concrete. By referring to Fig. 4, the flaring cross-section of the trench in the left channel shows the result of this method of excavation. Mr. Cushman, who arrived at the dam site before any concrete was placed, gave this matter the closest attention, had all the loosened material removed, and the bottom of the trench hand-picked to a depth of from 1 to 2 ft. below the effect of any shots. That the blasting had nothing to do with the free leakage of the holes in the left channel is readily seen by referring to the tabulation on page 23,* or to the curves on Fig. 10, which indicate that the leakage, even of the primary holes, was insignificant until a depth of 30 ft. below the cut-off had been reached.

With a competent powder man in charge as foreman, there would seem to be little danger of doing irreparable damage to the surrounding rock, and against the more than one able engineer, whom Mr. Hulse states that he has heard argue against the practice, the following editorial comment† regarding the grouting at Lahontan, is quoted:

"On this dam the estimate of the saving made was only $3 000, compared with the cost of trenching and filling with concrete to the same depth. Many engineers would prefer the trenching method where the difference is so small."

In justice to the engineers of the Reclamation Service, it should be stated that it was the saving of time rather than money, which led to the adoption of the grouting programme, which, as the cut-off was already 30 ft. deep, really amounted to making assurance doubly sure, or super-insurance against leakage.

As to the general proposition of trusting to the grout to form a

* *Loc. cit.*

† *Engineering News.*

Mr. Rands.

cut-off, even to the closing of surface seams, in lieu of the usual concrete-filled trench, there is certainly room for difference of opinion. A case in point is that of the dam at Austin, Pa.

The failure of this dam, in the start at least, seems to have been due to the slipping or sliding of the immediate stratum, on which the dam stood, over the stratum next below, the pressure of the water in the pond having changed the clay in the seam between the strata into an excellent lubricant. A concrete cut-off would undoubtedly have prevented the catastrophe, though it is hard to see how any amount of grouting could have altered the unfortunate result.

Mr. Fisher rather objects to the writer's expression to the effect that "most engineers will conclude that over a portion of the cut-off no grouting was needed, and that over other parts where it was needed, it did little good." This, of course, is only a matter of opinion, though it may be noted that Mr. Cushman, who is equally conversant with the Estacada conditions, considers the attempt there to have been, "to a large extent, futile."

Mr. Fisher also states that the engineers should be given credit for what was accomplished. The writer had no desire to take credit from any one, but he did feel that the Profession was entitled to the full facts concerning the Estacada grouting. Whether the grouting was carried to an unwarranted length and expense is again merely a matter of opinion; whether the method is good or bad, as applied to another structure, may be vital.

To Mr. Cushman belongs the credit for suggesting the possible shattering of the material between the drill holes in order that it might receive thick grout and form an effective cut-off, though this was not tried at Estacada, nor, so far as known, on any other work; to Mr. Cushman also is due the credit for suggesting the capitalizing of the loss through seepage and balancing it against the cost of grouting. Probably, also, more than he is aware, the writer is indebted to Mr. Cushman for ideas throughout the paper.

Mr. Coburn states it as his belief that the natural sedimentation, possibly accelerated by a deposit of suitable material above the dam, would have effectually sealed the foundation material without resorting to the grouting treatment. In reference to this, it may be of interest to consider the Crowley Creek Dam, a very thin concrete arch structure wedged between the rock walls of a box canyon in Malheur County, Oregon. This dam was designed by A. J. Wiley, M. Am. Soc. C. E., and concerning it, the following is quoted from the Third Biennial Report of the Oregon State Engineer:

"During the first season's use there was a very perceptible loss of water which passed through seams in the lava and re-appeared below the dam, but this leakage has gradually lessened and is no longer of any moment."

Mr. Rands.

Considering those portions of the discussion contributed by members not connected with the Estacada Dam, there is much of value in those of Mr. Abbot and Mr. Souder, the former covering the grouting of Lock and Dam No. 2 in the Mississippi between St. Paul and Minneapolis, and the latter that of the Hinckston Run Dam, in Pennsylvania. These seem to be the pioneer examples of grouting in America, and it is gratifying that they are now so fully made a matter of record.

In his discussion, and in his earlier excellent paper on the Fremantle Graving Dock,* Mr. Ramsbotham has given a view of grouting from another angle, and he, too, because of designing his own grouting machine, deserves to be classed among the pioneers.

Mr. White has summed up the subject so fully in accord with the writer's idea, and in so much better and so much more concise language, that to comment would be to detract.

Mr. Paul's description of the grouting of the great Arrowrock Dam, and the conclusions drawn therefrom, are valuable evidence. It is interesting to note how nearly parallel Mr. Rippey's original recommendation as to the necessity of "actual demonstration in advance of construction" is to Mr. Paul's final injunction to the effect that "where grouting is actually needed, it is unsafe to depend on it, except after convincing evidence, at the site, that it will give the results desired."

It is not proper to close this discussion without some additional statement as to the safety of the Estacada Dam. As has been said, no springs have appeared below the dam as a result of its construction, and the fact that the pressure of the water in the hole put down inside the dam was sufficient to cause the water to rise within 13 ft. of the level of the water in the pond, is good evidence that no seepage or leakage has occurred. It is true that there is the chance that the water under so great a pressure may find an outlet, but, as time goes on, and the natural silting processes take place, the danger of this becomes less likely.

The type of dam renders negligible any danger from uplift, though it may be pointed out that no seepage was encountered from the holes put down inside the dam until more than 20 ft. of rock had been drilled through, and it was not until a depth of 60 ft. of rock had been reached that the pressure became sufficient to raise the water to the height noted. The weight of this rock, plus the weight of the dam resting on the buttresses with 5-ft. footings, spaced 18 ft. from center to center, plus the resultant of the water pressure acting on the 45° deck, effectually negatived any upward pressure from the water under the dam. It is perhaps unfortunate that the term "leakage" has been applied to the water which it has been possible to "lose" through the holes in testing. For, as Mr. Fisher has pointed out, the conditions are much more favorable for leakage or loss of water, through

* *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 1942.

Mr. Rands.

the rock with a 50-ft. hole penetrating its interior, than when later the pond is filled and no such penetration exists. Also, as Mr. Fisher has pointed out, the leakage appears to be small indeed when expressed in second-feet, or rather as a fraction of a second-foot, instead of gallons per minute.

The writer feels that this explanation is due in order to counteract any inference that might be gained to the effect that, because of the failure of the grouting to do all that was hoped for it, the dam is unsafe.

In conversation, Mr. Coburn, shortly after the appearance of the paper and the first of the discussions, said that, in his opinion, the question of grouting appeared to be just where it was before, that is, it is still incumbent on those advocating grouting to do all that they claim for it to prove their point; and this seems to be the case.

Consider the dams that have either partly or entirely failed during the last few years in America. We have the Austin, Pa.; the Austin, Tex.; the Pittsfield, Mass.; the Port Angeles, Wash.; and the Stoney River, West Virginia. Of these, that at Austin, Pa., has already been considered. The dam at Austin, Tex., though, according to the late Joseph P. Frizell,* M. Am. Soc. C. E., stood on material in which "lay strata hard and soft", and though there was a single leak under the dam from the time of its completion to the day of its failure, through which flowed 6 000 000 gal. of water every 24 hours, the real cause of the failure seems to have been due to the undermining effect of the water at the down-stream toe, which, months before the dam failed, had progressed so far that bottom could not be touched with a 10-ft. pole. Had the apron been added, as recommended by the engineers, the dam in all probability would not have failed. Some may say that the lack of the apron was only one of the causes which produced the failure, and that, had some means been used to seal the material effectually along the up-stream heel, the uplift pressure would have been much reduced and the dam would not have failed at the time it did. In reply, it is only necessary to point out that grouting has not yet shown its adaptability for correcting "soft strata".

The other three dams mentioned, namely, the Pittsfield, the Port Angeles, and the Stoney River, all failed from one and the same cause—failure to carry the excavation to bed-rock. Grouting would probably not have put off their failure by so much as one day, though all might have been saved by a proper back-fill, as was suggested by Mr. Coburn for Estacada, which treatment has been most thoroughly covered in several articles by Mr. G. W. Bligh, appearing at various times in the engineering papers.†

* "Water Power," by Joseph P. Frizell, 3d ed., p. 245.

† *Engineering News*, December 29th, 1910, p. 708; February 6th, 1913, p. 226.

Mr. Rands.

The real trouble with grouting is that it is too easy to think about doing; too easy, when a stratum of poor material is unexpectedly encountered in making the excavation, to set in a few pipes and go ahead with the construction, trusting to the grouting to make it right—a practice on a par with the oft-repeated expedient of putting an additional nail or two in the end of a board because of a knot or a rotten spot in the middle.

Even admitting that, because of lack of sympathetic co-operation or from any other cause, the grouting at Estacada was not done as well as it should have been, the fact that a colossal attempt, costing nearly $70 000, resulted in indifferent success, goes a long way toward proving that grouting is far from being yet a very strong competitor of the conventional cut-off. Or, considered at its best, it seems a far call from any results that it has yet achieved to the day when any material requiring treatment to carry the load of a great dam, and make it safe against the tireless, insistent, searching pressure of the water, can be rendered secure by grouting.

It is true that in the discussion mention is made of a certain foreign dam, the name and location of which the writer was not at liberty to give, wherein the grouting had been a "complete success". It is also true that those who advocate this system of foundation treatment qualify their recommendations with the provision that the sufficiency of the grouting to do the work must be demonstrated in advance of actual construction. It must be remembered, however, that only sometimes are recommendations acted on, and that even the Estacada Dam, for the benefit of which this rule was first proposed, because of the insistent demands of the owners for early power, was made an exception thereto.

The writer still believes that grouting has a legitimate field in preventing possible seepage and in solidifying the material under a solid dam in order that the uplift due to water passing under the concrete cut-off may be reduced. In short, as an agent to "make assurance doubly sure".

He regards as premature and unwarranted, by anything it has yet achieved, to claim for the grouting process the formation, in any but the most favorable material, of an effective cut-off. The real danger lies in dams of 40 to 75 ft. in height, the construction of which may be undertaken by companies of limited means, and, in the design and supervision of which, engineers of limited experience may be engaged. It is in the construction of these dams that there is danger in expecting too much of grouting, or, as Mr. White puts it, in making "a sort of fetish" of it.

The result of this, when poor material is encountered and an insistent and impatient owner is to be satisfied, will be to set a few grout casings, but the sequel may be disaster and death.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

THE GAUGE OF RAILWAYS, WITH PARTICULAR REFERENCE TO THOSE OF SOUTHERN SOUTH AMERICA.

Discussion.*

BY MESSRS. JAMES ALEXANDER SMITH AND F. LAVIS.†

Mr. Smith.

JAMES ALEXANDER SMITH,‡ ESQ. (by letter).—The matter of the gauge of railways is of peculiar interest in Australia. It has been claimed, as an argument in favor of the 4 ft. 8½-in. gauge, that Australia has adopted this width, but this is not so. Some misunderstanding may have been caused by official publications issued by the Commonwealth Railway offices. These publications have been the subject of a Parliamentary enquiry, and it has been shown that they are inaccurate, and that the signatures of State Engineers, who have been consulted, are appended to matters in respect to which they did not concur, and that their protests were suppressed.

The writer suggests that, in the interests of accuracy, it be recorded that Australia has not, either in respect to the several States or the Federal Government, adopted the 4 ft. 8½-in. or any other uniform gauge. The facts, at the present date, are as follows:

Early in 1914 a conference of the Premiers of the several States —which control all the Australian railways in operation—and of the Commonwealth Prime Minister, was convened and held, to deal finally with the question of a uniform gauge for Australia.

Several of the States favored the appointment of an independent commission of railway experts, representing Great Britain, Europe and America.

---

* Continued from September, 1914, *Proceedings*.

† Author's closure.

‡ Melbourne, Victoria, Australia.

Mr. Smith. The Prime Minister advocated the remission of the question to a lay "Interstate Commission," recently appointed to advise regarding trade and fiscal matters affecting more than one State. This was agreed to, and the conference disbanded.

Some months later, when interrogated in the Federal House, the Prime Minister stated that he had found that, under the Constitution, the Commission had no jurisdiction unless specially authorized by a vote of the House, therefore that the action just mentioned had been *ultra vires*. He also stated that he did not propose to seek the authority of the House, which has since been dissolved.

In the interim the Commonwealth Government has decided to reticulate the whole of the great "Northern Territory" with railways of 3 ft. 6-in. gauge. That is also to be adopted for the North to South Trans-Continental. Commitments on that basis are being entered into.

Simultaneously, the Commonwealth is constructing the East to West Trans-Continental on a 4 ft. 8½-in. gauge. This road connects, to the East, with the 5 ft. 3-in. system of South Australia and Victoria; and, on the West, in default of a specific arrangement by the Commonwealth as to gauge and financial support, Western Australia is preparing to construct its great extension of the Trans-Continental to the Coast on the 3 ft. 6-in. gauge.

The position is most deplorable, and indicates that unity of gauge is anything but an accomplished fact in Australia.

Mr. Lavis. F. Lavis,* M. Am. Soc. C. E. (by letter).—Some surprise has been expressed to the writer by certain engineers, who have had much experience in railroad construction, as to the necessity for any such elaborate discussion of the gauge question at this late day, and, even supposing the question to be of interest elsewhere, why the matter should be thought of sufficient interest to warrant the publication of such an elaborate paper by this Society.

Of course, the latter criticism needs no argument for its defence, the Society is too large and important to confine its activities necessarily to matters of concern only to the United States, and the great interest which has been developed by the citizens of this country in South America since the presentation of the paper is ample justification, if any be needed, for the publication of any matter of interest in regard to the development of this vast area, in which the United States, and incidentally the engineers of this country, are bound to play an important part.

In regard to the first criticism, the writer admits that it must seem strange to American engineers, or to any others with knowledge of American railway methods, that it was considered necessary to go into so much detail in regard to many things which in the United

* New York City.

States are accepted as axiomatic. A study, however, of the voluminous discussions of the past ten years and up to the present, in regard to the gauge question in India and Australia, two countries where the matter is now of vital interest, will show that most of the fallacies in regard to gauge—if not all—which we believed long ago disproved, are still held by many engineers as well as laymen by no means obscure. The persistence of the curve fallacy, as shown by some of the discussions, in spite of the concrete examples given in the paper, is only one instance of this. Mr. Lavis.

The present status of the gauge question in Australia is shown by Mr. Smith's discussion, which apparently indicates that in spite of a former decision to do all that was possible to unify the gauges, feverish activity seems to have developed in just the opposite direction, namely, to build as many lines as possible of different gauge.

Almost coincidently with the presentation of this paper, Sir Guilford L. Molesworth, one of the most prominent engineers connected with the administration of Indian railways, read a paper* urging the importance of the immediate consideration of some measures looking to the ultimate unification of the gauges of that country, but complicated by this question of gauge.

The present temporary stagnation of railway construction in South America is bound to be followed sooner or later by an era of activity. It seems to be probable that North American engineers will have a larger voice in these matters than they have had hitherto, and this seems especially appropriate inasmuch as the problems to be overcome are largely those which they have had to solve in the United States and Canada.

The writer is quite willing to admit that the criticism advanced by Mr. Henry is to some extent well taken, and that the estimates used in the paper of the difference in cost of construction of new lines due solely to difference of gauge, are "liberal" in so far as they exaggerate, if anything, the relatively higher cost of the wider gauge; but, inasmuch as these estimates were made with a view of their probable application to actual construction in a foreign country, it was hardly thought desirable to afford opportunity for criticism on the opposite side.

The problem of deciding between the narrow-gauge and 4 ft. 8½-in., or wider, does not seem to the writer to admit of much further discussion or doubt, but the matter of deciding between the 4 ft. 8½-in. and the 5 ft. 6-in., is one of considerable difficulty.

If the Argentine alone is considered, of course, it seems desirable for many reasons to adopt the 5 ft. 6-in., not because it has any greater capacity, but because it is established, and, for new extensions, its

* "The Battle of the Gauges in India," *Journal*, East India Assoc., London, England, April, 1914.

Mr. Lavis.

additional cost over the 4 ft. 8½-in. would be comparatively little. Mr. Hill's opinion in regard to this is worth noting; though a lowered center of gravity, as has been shown by the effect on track of some of the electric locomotives first designed with very lower centers of gravity, is not an unmixed blessing.

The writer's study of the possibility of applying some scheme of unification of gauge to the whole of that portion of South America south of the Valley of the Amazon (or even including part of the southern water-shed), on account of the political subdivisions and the apparent difficulty of coming to any agreement between so many diverse interests, may be considered rather fanciful. The fact, however, that as long ago as 1890, a commission headed by as eminent an engineer and railroad man as the late Alexander J. Cassatt, and working under an agreement participated in by practically every country in the Western Hemisphere, investigated the possibilities of constructing a line, or series of lines, of railway linking up at least all the capital cities, shows that there has been for many years, in the minds of far-seeing men, a vision of a system of railroads covering the two continents, which will permit rapid and easy inter-communication between all parts. Considering, therefore, this vast area south of the Amazon and east of the Cordilleras as a single geographical unit to be covered by a network of railways, all of the same gauge and suited to modern conditions of transportation, such a system can hardly be regarded as entirely visionary.

Whether it be possible finally to reach an agreement for this purpose is difficult to determine, but the writer believes that if it may be, that, for reasons given, the 4 ft. 8½-in. gauge, as Mr. Hill states was true of the United States, is all that the "traffic of the country could bear". The idea that the constructors of the broad-gauge lines of the Argentine would not sit passively by without attempting to throw out extensions toward the north is one of course to be considered. The broad-gauge lines of the Argentine are to-day the most important group of transportation lines south of the United States, but this is only one item in a very complex problem which would have to be worked out to accomplish a desirable result, and, though not impossible of solution, it will require more than the efforts of any one man. The writer can only hope to have called attention to the problem and to some of the factors which will have to be considered in its solution, if a solution is ever desired.

The discussion by Mr. Corry is interesting in view of his long experience with the operation of the standard-gauge mountain roads of Southern Peru. Of course, it is true that railways should be built—as E. H. McHenry, M. Am. Soc. C. E., put it a long time ago—in such a way that the dollars spent for their construction will earn the most interest, and it is easily conceivable, and is admitted in the paper,

that there are many mountain districts where narrow-gauge lines to be used as feeders may be built to advantage. Mr. Lavis.

Mr. Corry shows that, on the standard-gauge lines of the Southern Peruvian Railway, curves of 328 ft. radius are successfully operated, and states that it is debatable whether it would have been advisable to have built the line with a gauge of 3 ft., using curves of 265 ft. radius. He states that it is axiomatic "that a considerable amount of traffic, even in a mountainous country, can be handled at less cost per ton per mile on a standard gauge than on either of the narrower gauges, and the standard is the more economical even if it does cost more to construct."

Yet Mr. Corry questions the advantages of the standard-gauge for mountainous regions, for the reason that sharper curves can be used and thus the graduation item can be reduced. This, in spite of the fact, as stated in the paper, that locomotives weighing 850 000 lb. are operated on the standard-gauge line of the main line of the Atchison, Topeka and Santa Fé Railroad on curves of 357 ft. (109 m.) radius, and the citation of the traffic handled on curves of 100 ft. radius on the rapid transit lines of New York City. For regions which may be served by lines of less than meter-gauge, the possibility of the use of excessively sharp curvature may perhaps be at times a controlling feature, but such lines can hardly ever be considered as main lines of transportation, and though they have their uses, and the Antofagasta is an excellent example of the value of 2 ft. 6-in. gauge, though it is now being forced to widen it, and will eventually be forced to widen again or double-track, they hardly enter into the consideration of the development of the transportation system of a continent.

Mr. Corry's illustration of the difference in cost between a line of 3-ft. gauge with 3% grades and curves of 120 m. radius, and one of 2 ft. 6-in. gauge with 5% grades and curves of 50 m. radius, can hardly be considered as having any bearing on the question of the difference in gauge, even as between 2 ft. 6-in. and 3-ft., inasmuch as the difference between the 3% and 5% grades might easily have caused all the difference in estimated cost.

It would be extremely foolish, of course, to say that standard-gauge, either 4 ft. 8½-in., or 5 ft. 6-in., should be used everywhere, and under every conceivable condition, and there is no question at all that Mr. Corry is right in pointing out that there are some places where it may be advisable to use a narrower gauge; but, as he also intimates, there is often an ultimate economy, by reason of the reduced operating expense of the wider gauge, even (and the writer believes, often more especially) on mountain lines.

Mr. Foster also seems to believe, at least to some extent, in the benefits to be derived from the possibilities of using sharper curves for narrow-gauge. This, perhaps, is due to some extent to the limitations

Mr. Lavis.

imposed on the 5 ft. 6-in. lines of the Argentine, by reason of the construction of their rolling stock, as well as by Government regulations. Perhaps, however, when opportunity permits the further consideration, by the Government and the railways of the Argentine, of the desirability and necessity of the use of automatic couplers, this will eventually require the abolition of the side-buffers and the use of a coupling which will—as it does in the United States—permit the operation of much heavier rolling stock over quite as sharp curvature as that in use on the meter-gauge lines of the Argentine. It is true that, on the meter-gauge, well-maintained curves of 3 300 ft. radius can be taken comfortably at full speed, but this is also true of the 4 ft. 8½-in. gauge, and at much higher speeds, as shown by actual practice, and the writer believes that it would be equally true of the 5 ft. 6-in. gauge, with rolling stock of the type in general use in the United States. In regard to turn-outs for the use of main-line trains, and for general use in yards occupied by passenger trains, there has been a general trend in the United States toward the use of No. 8 frogs (or 1 in 8) as a standard, in preference to those of greater angle.

Mr. Osborne evidently has not read the paper carefully if he understands, as he states, that the writer claims that the 4 ft. 8½-in. gauge in the United States and Canada shows the railway systems of those countries to be the most efficient in existence, and that this efficiency is due largely if not entirely to their gauge.

The mere fact that the writer suggests the adoption of the 5 ft. 6-in. gauge, when considering the Argentine alone, is sufficient to show that he considers efficiency with this gauge entirely possible and practical. All that is said in the paper, indeed, is that the 5 ft. 6-in., though costing more to build, offers no advantages as a transportation machine that the 4 ft. 8½-in. does not possess, nor does it permit of cheaper operation. There are doubtless many individual cases of railroads on which traffic is handled at a cost even lower than the average of the United States, but, speaking generally, it is true that, taking the country as a whole and considering the volume of traffic handled, the transportation of bulk freight is done at a lower cost here than elsewhere. If Mr. Osborne will read the paper carefully, however, he will note that it is claimed that this is due principally to the ability to handle very heavy trains, and has been brought about very largely by the increase in average train loading, in spite of great increases in cost of wages, etc. There is no claim in the paper that this economy, or perhaps more, might not have been attained on the 5 ft. 6-in. gauge, though, most assuredly, it could not have been attained on the meter-gauge. The claim is, however, that the extra cost of the 5 ft. 6-in. is not warranted, as it is not compensated for by any decrease in operating cost or any advantage over the 4 ft. 8½-in.

Mr. Lavis.

Mr. Osborne is quite mistaken in assuming that the area south of the water-shed of the Amazon is to any large degree within the tropics. Rio, which is taken as approximately the northern limit at the coast line, is just within the tropics, and though the interior part of the area under consideration runs somewhat farther north (that is, toward the equator), it is at an elevation of 2 000 ft. or more, and has a salubrious climate.

It is entirely improbable, as Mr. Osborne states, that the traffic of this vast area will ever approach the density of that of the United States, inasmuch as it is improbable that manufactured articles will be produced in it in any quantity, but nearly all the traffic is bulky and can only be hauled long distances cheaply—and it must be handled cheaply to move it—in cars of large capacity in comparatively heavy trains. The bulky agricultural traffic of India has been given by more than one prominent engineer and railway official as the reason for the adoption of the 5 ft. 6-in. gauge there, and though undoubtedly it is possible to handle heavier equipment and trains on the 5 ft. 6-in. than on the 4 ft. 8½-in., it is a fact that it is not done, so that it is considered that the 4 ft. 8½-in. is sufficient for these countries, and there is nothing to be gained by using the 5 ft. 6-in.

Time and time again the engineers and military authorities of India have advocated what Mr. Osborne does, that if it is not possible to unify the gauge, each gauge should be confined to a definite area; this has always been the cry, but it has never proved practical to do it, and the meter-gauge lines of Northern India are to-day agitating the matter of obtaining their own outlet to the coast, and Mr. Smith's testimony shows the effect in Australia. It is quite possible, of course, to admit—with Mr. Osborne—that under certain conditions all gauges are good and capable of efficient operation, but it is undoubtedly the consensus of opinion, of railway operators as well as of engineers, that the broad-gauge is a far more efficient transportation machine than the narrow-gauge, and enough more so in almost every instance to compensate for the comparatively very slight additional cost of construction, and as between the 4 ft. 8½-in. and 5 ft. 6-in. gauges, there is no particle of evidence to show that the former is not as efficient as the latter.

It is a fact that the 4 ft. 8½-in. gauge has served its purpose admirably, the effect of the introduction of a wider gauge anywhere has almost invariably been the subsequent introduction of the narrow-gauge, therefore, the writer feels that he is not only following well-established precedent in advocating the 4 ft. 8½-in. as the standard, if it be possible to unify the gauges of Southern South America, but also that this precedent is founded on wide practical experience.

REINFORCED CONCRETE DOCKS: FOREIGN AND AMERICAN STRUCTURES. FAILURES, COSTS, AND GENERAL CONSIDERATIONS.

Discussion.*

By W. J. Douglas, M. Am. Soc. C. E.

Mr. Douglas.

W. J. Douglas,† M. Am. Soc. C. E. (by letter).—There have recently been completed, for the Port of Havana Docks Company, two large deep-water piers, built entirely of reinforced concrete. These are the San Francisco and Machina Piers, two- and four-story reinforced concrete structures with 85-ft. concrete pile foundations, in deep water and soft mud. Two additional piers are planned to be built at some future date.

The piers were designed and the construction directed by Barclay Parsons and Klapp, Consulting Engineers, of New York City. The contractors were MacArthur, Perks and Company, also of New York City.

Although these piers, with the large connecting warehouse along the shore, contain many features of interest to engineers, the present discussion will be confined to the pile foundation.

The piers are 164 ft. wide and from 660 to 680 ft. long, the distance between them being 262½ ft. The depth of the water varied from 20 to 40 ft., and the piles were driven into 15 to 20 ft. of soft mud which covered a firm sand and clay bottom.

Prior to deciding on the use of concrete piles, careful consideration was given to various other types of foundations, but these piles were finally selected because, of all the permanent types of foundations,

* Continued from September, 1914, *Proceedings*.

† New York City.

Mr. Douglas.

they were the cheapest. Marine borers are particularly destructive in these tropical waters, and this made it quite impossible to use wooden piles.

The length of the piles varied from 45 ft. inshore to 85 ft. in the outer 300 ft. The variation in length was made in 5-ft. increments. The piles were square in cross-section, the length of the sides being 16, 18, or 20 in. The piles were reinforced longitudinally with from 4 to 6-ft. plain round steel bars varying from $\frac{3}{4}$ to $1\frac{1}{4}$ in. in diameter. These main rods were hooped with $\frac{1}{4}$-in. square rods every 16 in. in the length of the pile, except where the rods of opposite faces lapped, and there the hoops were 4 in. from center to center. In the lower 3 ft. of each pile the hoops were 6 in. from center to center, and in the upper $3\frac{1}{2}$ ft. there was a special rod reinforcement, basket-like in appearance, in order to resist the shock of the hammer. The details of the reinforcement are shown on Fig. 1.

For handling the piles, the longitudinal reinforcement was proportioned to the bending-moment stresses when the pile was supported horizontally from two points which were located so as to make the negative moments at the points of support about equal to the positive moment at the middle. Two methods of handling the piles were predetermined when they were designed. Fig. 2 shows one of these methods; the pile is about to be lowered into position by the derrick boat. The stresses resulting from handling the piles in this manner, and without allowance for impact, were 20 000 lb. per sq. in. of steel. In a few sample piles, high unit stresses were tried, but it was found absolutely impractical to handle them where the stresses were greater than 25 000 lb., but it was perfectly safe where they were somewhat less. In handling some of the first piles, before the hoisting engineers had had experience, the whipping of the piles caused failure, but this trouble lasted only a very short time, the men learning very quickly how to handle them properly. Experiments with hollow piles of somewhat lighter weight were not successful, as they were broken either in the handling or the driving. The heaviest solid pile weighed about 18 tons.

The casting was done in a yard especially equipped for the purpose. A level platform was first prepared on which the piles were cast, each being separated from the adjacent pile by a thin collapsible form. The piles were then constructed in layers, the second layer not being placed until the first one was reasonably hard. Each pile was numbered, and it was not touched for at least 3 weeks after it was cast. When sufficiently hard the piles were lifted and transported by overhead, electrically-operated, traveling cranes. These cranes were intended to be used on the piers after all the pile work had been completed. The pile casting area was roofed over in order to protect the laborers and the product from the sun.

Mr. Douglas.

PORT OF HAVANA DOCKS COMPANY
HAVANA, CUBA

FIG. 1.

Mr. Douglas.

Contrary to the usual custom, all the longitudinal rods were welded. The welding was done by Spanish blacksmiths, who were particularly efficient in such work. The reinforcement gave no trouble on account of the welds.

The piles, after hardening, were carried to the site of the work either on the derrick boat, Fig. 2, or on a lighter. They were lowered into place by the derrick, as shown on Fig. 3. The fall line was released quickly and the piles sank into the soft mud under their own weight, often penetrating it to as great a depth as 20 ft.

The pile was held by a sling fastened to pins which extended through two holes in the pile, provided in casting it, for the purposes of handling. Each hole was lined with a steel pipe in order to prevent injury in handling. After the pile had been dropped into place, the sling was released, and a 6-ton, No. 1, Vulcan, steam hammer, Fig. 4, suspended from the derrick boom, was placed on top of it. A rope mat was used to cushion the hammer blows, and each pile was driven with an average of 500 blows into a hard stratum until it gave a refusal of about ½ in. under the last ten blows. Occasionally, satisfactory refusal was not obtained, and, in such cases an additional pile was driven alongside to insure proper bearing capacity. There were 4 000 piles driven in this manner; they were arranged in clusters varying from 4 to 24. A number of piles were tested. Up to 60 tons there was very small settlement, the piles practically recovering when the test loads were removed. Each pile has a theoretic load of 40 tons, consisting of approximately 15 tons of dead load and 25 tons of live load. The tops of piles that could not be driven to the depths planned were cut off with a pneumatic chisel. Some trouble was caused by the concrete spawling off at the corners under driving. This was remedied by introducing ¼-in. square diagonal steel ties about 12 in. from center to center.

It was also found that calcarious sand gave very much stronger pile heads than ordinary sand or stone dust. The stone dust was particularly unsatisfactory, resulting in a great many breakages of the pile heads under driving.

Piles were driven at an average rate of about 12 a day. Only two lines of batter piles at the outer end of each pier were used, notwithstanding the great depth of water. For the lateral stiffness of the piers, the designer depended almost entirely on the resistance of the floor as a cantilever anchored in shore. This assumption seems to be warranted fully by the stiffness of the piers. As the concrete floors are heavily reinforced, it was assumed that any shock of boats against the pier would be transferred from the outer end, through the concrete and steel reinforcement, to a point where the piles were sufficiently short to insure ample stiffness. Fig. 4 shows the method of driving the batter piles.

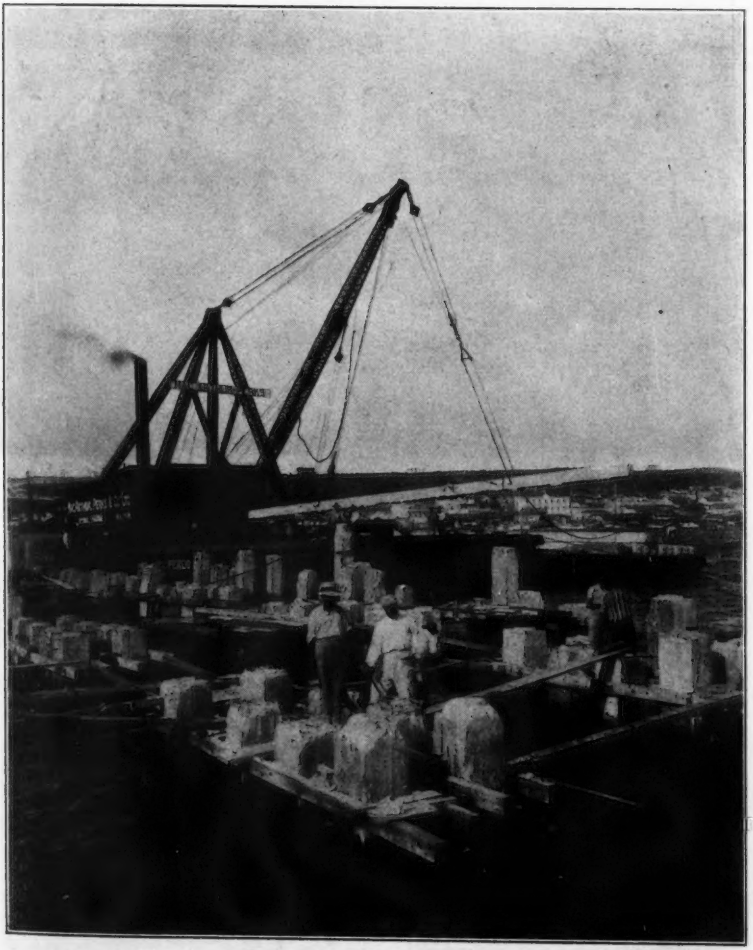

FIG. 2.—METHOD OF HANDLING THE PILES.

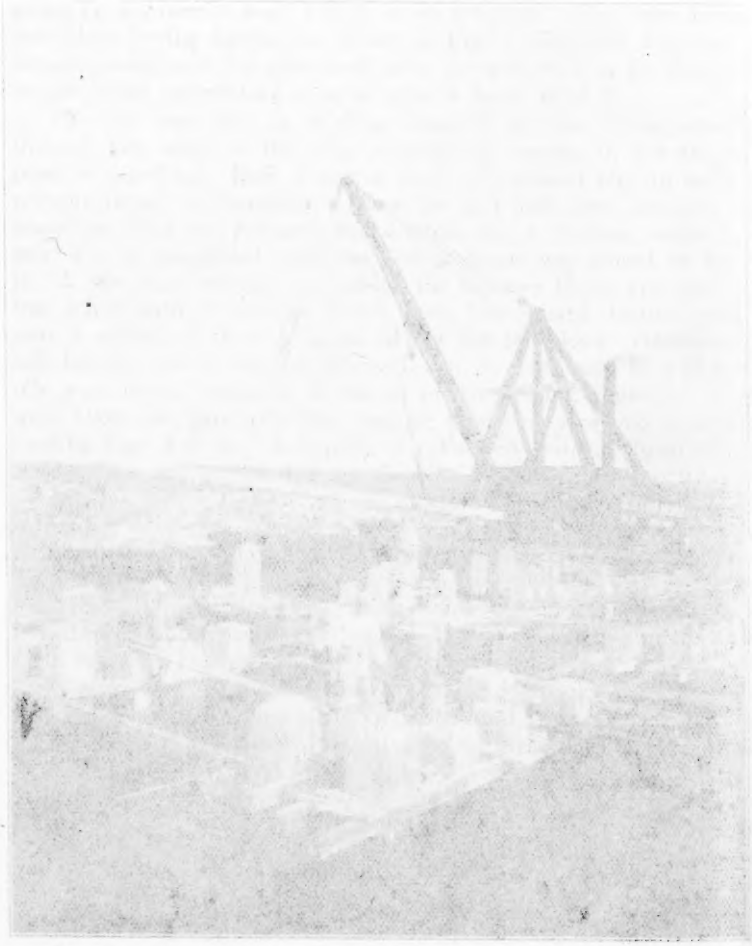

FIG. 3.—LOWERING A PILE INTO PLACE WITH THE DERRICK.

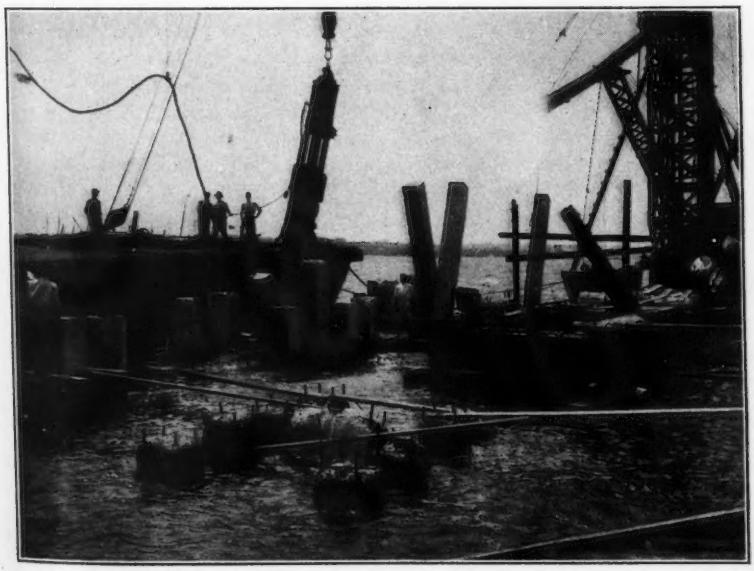

FIG. 4.—METHOD OF DRIVING THE BATTER PILES.

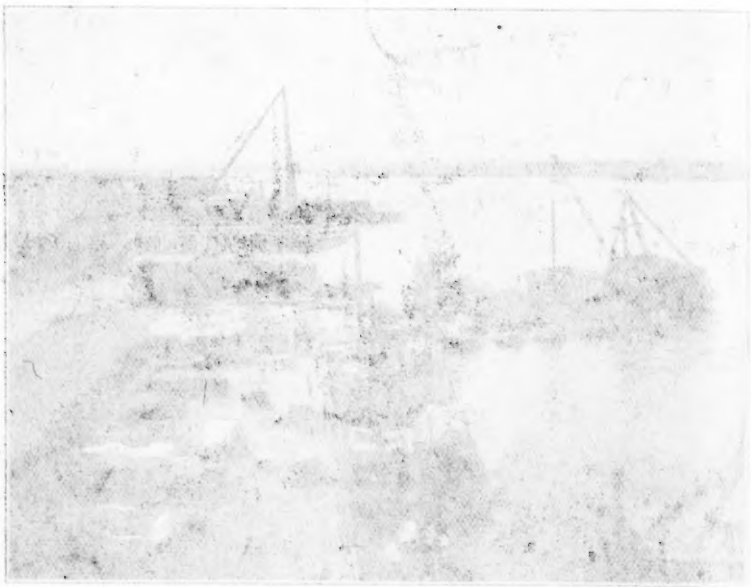

Mr. Douglas.

Previous to designing and constructing these piers, an examination was made of some concrete wharves in which the longitudinal reinforcement above water had caused the steel to rust and spoil the concrete. Quite a number of rods were exposed to sea action. This was due to the fact that the steel had not been spaced carefully. Extreme care was taken in this Havana work to keep the longitudinal steel well covered with concrete. In other cases it had been observed that, where tie wires had been left protruding from the faces of the piles, rusting had taken place and, of course, had worked in until there was disintegration of the concrete. The piles in these piers have been examined from time to time and have been found to be in perfectly good condition. At present, of course, they are fully covered with marine growth below the water line.

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

SOME PRINCIPLES RELATING TO THE ADMINISTRATION OF STREAMS.

Discussion.*

By George P. Decker, Esq.

Mr. Decker.

George P. Decker,† Esq. (by letter).—The civil engineer has addressed himself in earnest to the water law problem. There are signs of it on all sides. Lawyer and layman must welcome the fact. The uses to which surface waters in natural bodies are put, has distinguished water from upland radically in connection with private rights. Water may be the subject of certain exclusive individual uses, but not more so than air. The uses of water, in most cases, are enjoyed in common by all members of the community, as are the uses of the air. Want of fixity of water distinguishes its character from that of land. The latter may be subdivided and the subdivisions may be enjoyed exclusively and harmoniously by individuals, but the former may not. These differences have resulted generally in recognition, sooner or later, of a necessity for governmental administration over water uses.

In newly settled countries, such as our States were recently, this administration begins with simple rules, and these increase in complexity as need for all the various water uses increases. Differences in natural surroundings lead to a different order in the development of such rules. In arid regions rules applicable to irrigation may be first developed, or may be the only ones developed. Along tidal waters rules are needed as to the use of riparian frontage in commerce much more than on interior waters. On power streams rules of a different sort, when developed at all, are found, and these are adjusted to those for other uses, according to the order or extent of the development of

* Continued from November, 1914, *Proceedings*.
† Rochester, N. Y.

Mr. Decker.

local industries. The common right of fishing is world-old; yet we have had State judges who have denied that it existed as to fresh waters. The denial of that common right was quite necessary in the effort to sustain the argument for denying the public right to water-power uses. Rules for the regulation of navigation, a common right, were developed at an early date, and so was active governmental administration over that right, because, in early days, of public dependence on streams for travel; the small stream as well as the large one. At first, the private user of water power was an outlaw; the power use might be enjoyed only where, and so long as, it did not interfere with boating—then the more important use. The power use, however, was soon legalized in all the States by express statutes, in order to protect the private user from prosecution in the name of the public, for his use was not at all in common with that of other members of the community. His use was exclusive, and, because of the necessary interference with the stream, was hostile to community uses for boating and also for fishing. The legalizing of that use by him was merely a temporary permission, a franchise, vouchsafed by the public. As long, however, as there was power enough, generally speaking, for every one, anything like real governmental supervision over it was in abeyance. In the United States that condition has lasted from the beginning almost to date, as to all active governmental supervision over public uses, municipal uses so-called and navigation being general exceptions, and irrigation a special exception in arid States.

Absence of supervision invited wide-spread litigation between conflicting private interests, and from that grew up a body of judge-made laws as to water uses, which came to constitute our water law so-called, but the law as recognized and widely applied. Mr. Johnston's criticisms of the quality of that law are admirably put and wholly justified. The only water uses in the Eastern States, which have demanded governmental supervision, so that these uses might be equitably enjoyed, were those of navigation and for municipal purposes. In applying that administration, however, the public was confronted with strange doctrines developed in the judicial decisions which had accumulated. It found that the exclusive use of a stream for power, enjoyed by the miller, had been recognized by the Courts as having a foundation in private property, as a vested right, not only as against his private neighbor, but as against all the rest of the public represented in its sovereignty by Government. That doctrine has been repudiated very recently by the United States Supreme Court in the Chandler-Dunbar Company case, arising at Sault Ste. Marie, and at intervals in earlier cases, some of them in the Courts of various States.

The enormous population with which we are now confronted, presenting itself almost everywhere, makes its own demand for a common

Mr. Decker.

enjoyment of the naturally public uses of water and for the enforcement of the public right thereto. We face a necessity, therefore, for active governmental administration of all such uses, for without it any real public enjoyment is quite out of the question. The rights of the public, of course, will be respected. That they should be disregarded for long, after enjoyment of them has become essential to public welfare, is impossible to conceive. No judge can rule irrepealably that these uses shall, for all time, at this place or at that, constitute private property in the few owners of adjoining upland. A new judge can be chosen who will overrule him. The development of the policies to be followed and the methods of administration of the various uses to which the public is entitled in bringing the common right or benefit to all, are among the most important tasks confronting the American people. The Engineering Profession, of course, must play its part. It is, in fact, the only profession qualified to-day to undertake that task. The department of the law which the legal profession has most ignored is that which deals with waters. No student entering that profession, up to the present, has had facilities for specializing in the law of waters, if he had desired. In the course offered by law schools, the law of waters is not usually dignified with provision for special instruction. Few practitioners have been in such circumstances that they could devote themselves specially to this subject. The water cases which have come before the Courts have been taken there by lawyers who in almost every instance were engaged in their first and last water case. The judge who decided a water case and who was sure to write an opinion, possibly—if not probably—was deciding his first and last water case. The result has been that there is no group of decisions so devoid of uniformity in the application of principles, so contradictory in the rules applied, as those which have gone to make up our water laws. No State has yet developed an adequate code of water laws. Such provisions as exist are usually found scattered through statute laws on other subjects, partly in the highway law, partly in the fish and game law, and partly in the municipal law. Only a civil engineer could have enjoyed a training and experience which would lead to the broad view of the subject revealed by Mr. Johnston's paper.

Mr. Johnston declares, as a first principle, the "public ownership of streams, lakes, and other bodies of surface water." That statement is useful at this time for the purpose of pointing out the common and great error involved in the statement that there is a qualified or almost unqualified private ownership. The use of the term "ownership" in connection with the subject of waters is always unfortunate, for it leads to misconceptions as to rights. It has been the layman, however, who was responsible for introducing this term in this connection, and he demands perhaps that it be used.

Mr. Decker.

It is desirable in the early stages of the effort to introduce a sane and just system of water laws, in order to eliminate all error possible to be implied in the statement of principles. The writer is of the opinion that Mr. Johnston's statement embraces such an element. Although water uses include many which are naturally to be enjoyed in common by all members of the community, there is one at least which is not naturally shared in this way under our system of private ownership of upland. The private owner of upland adjoining a stream is, quite independently of any act of his or of interference with a stream by him, served with those benefits which come through the saturation of his land by the stream. Such a benefit may justly be termed a natural one. It is one which the earliest agricultural settler relied on in securing his location. On that saturation, certain crops may depend. Riparian lots available for dwelling purposes may also have a value, due to the natural beauty of the contiguous stream. If so, that value was placed there by Nature. The stream may have a flow sufficient to be serviceable as a highway for boating, and, if it has, it was rendered so (opened) by Nature and not, as a rule, by Government, and is an outlet for the riparian land owner. In the case of highway openings by Government and the consequent invitation to settle and improve locations adjoining it, on the assumption that the highway will be perpetuated, it is recognized as just, if not indispensable, in closing the highway, or in shifting it, or in making successive changes in street grade, that compensation should be paid the abutting owner according to the injury which may result.

Diversion of a stream, then, without recognizing any obligation of the public to pay any damages—diversion on the theory that the public owns the stream (may destroy it to the extent of diversion) and render no compensation to any one—may involve injustice. This view is not based on recognition of any right in a private abutting land owner to interfere artificially with a stream, to divert, pollute, or obstruct it. The benefits referred to are such as are natural. If stream flow is to be diverted, then, by the public, in connection with an intended improvement facilitating public enjoyment of a common use or uses, or if a fraction of the flow is to be diverted, just damages according to the injury done should be paid. Such cases would be unlike that of the removal of a public building, artificial in itself, and where the gratuitous benefits which had come to neighboring lands by its construction would be lost on its removal. If taken away without compensation, there has been no injustice inflicted by the public. The law as administered has usually failed in the proper grouping of the cases which may afford a just ground for private damages against the public in case of complete or partial diversion of stream flow. If, however, damages are to be awarded when justly called for, as here

indicated, no serious obstacle in the way of the proper development of streams for their highest public usefulness would be presented. Mr. Decker.

The deterring of public improvements and of desirable governmental supervision over streams, has been due to the gross injustice to the public arising so often when damages have been awarded on the mistaken theory that uses which were in principle public and common were exclusively private, and private in perpetuity. The commonest example of that has been in case of power uses, for those, when treated as based on rights of private property, exclusive and perpetual, and then capitalized on the basis of their economic value, lead to startling figures in the making up of Court awards. If a private property right, as against the public, to use the water power of a stream for private purposes when the public needs it for lockages, cannot be sustained in justice, the same reasoning should apply where the public needs to divert the stream for municipal supply or for public power purposes. The stream in any such case would be taken for public purposes. It is for the Government, through its legislative department, to say which of all public uses shall have the right of way over the others. The riparian owner, from whose private frontage a stream is diverted, then should be paid no element of damages on the theory that as such land owner he has any exclusive right of use of the stream at his front for boating, for fishing, for drinking, or for artificial diversion for ends of his own. His damages in case of diversion by the public, when confined to loss of natural benefits, would consist of a nominal award in most cases, and a modest award in any case—so small in most cases that he would not seek an award.

A statement of principles based on recognition of the public right may be formulated as follows: Water uses which the public may enjoy in common are inalienable by Government for private benefit; they are subject at all times to regulation and administration by Government; if the public diverts a stream, it is liable for the injury, if any, produced by cutting off the natural irrigation or other natural benefits received from the stream by private riparian lands; if the channel below the diversion was navigable, the public is also liable for the consequent depreciation, if any, in the value of the lands fronting thereon; if the public is to acquire the right to divert forever, the damages, of course, will be estimated accordingly.

We seem already to have reached the time when denial, tantamount to betrayal, by State Courts of the public rights in respect to water uses must cease. Two regrettable instances of that have occurred recently, one in the Court of Appeals of New York, in the Fulton Light, Heat and Power Company case, the other in the Supreme Court of Wisconsin, in the Wausau Street Railroad Company case. In both these cases, the Courts applied the principle requiring protection of private property provided for in Federal and State Constitutions to

Mr. Decker.

safeguard it from unjust attacks by the public. It is now necessary that all concerned shall recognize the principle of greater sanctity and importance, namely, that public rights shall be safeguarded against attack by private interests. This principle is so fundamental the world over that constitution makers have not deemed it necessary to affirm it specially. It applies in the case of very many fundamental rights, of which no mention is made in written constitutions. It is gratifying to know that the highest judicial tribunal in the United States respected and enforced this principle in the case of a water use subject to public enjoyment, in the decision reached in the Sault Ste. Marie case in 1913 (229 U. S., 53), where a lower Court award of $500 000 against the public, in favor of a private corporation claiming a monopoly in the use of that river for private enjoyment, was reversed.

THE CONSTANT-ANGLE ARCH DAM.

Discussion.*

By Orrin L. Brodie, M. Am. Soc. C. E.

Mr. Brodie.

Orrin L. Brodie,† M. Am. Soc. C. E. (by letter).—The author is to be congratulated on the generally clear and concise treatment of the subject matter of his valuable paper and on his demonstration of the constant-angle arch principle. The paper has proved of particular interest to the writer as he has had occasion several times in the last few years to analyze the stresses in arched dams of different types. He gladly greeted the author's statement, early in his paper, of his presentation of a short-cut method for finding the distribution of the total load between arch and cantilever elements of the structure. The writer had developed a set of general formulas (including the moment of inertia of the horizontal section of the cantilever portion considered between vertical radial planes), so that a direct solution was possible for a dam of any vertical cross-section; but the actual computations prove long and tedious. The formulas referred to were developed along the lines laid down by the late R. Shirreffs, M. Am. Soc. C. E. In connection with this approximate short-cut method the writer, not having opportunity to try it for himself, would like to know whether it is applicable to a dam of any cross-section, say a spillway dam (at least 120 ft. high), arched, and which requires many changes, particularly at the top and bottom, in slopes of its down-stream face. He would also like to know what expenditure of time would be required in determining completely, by the ingenious short-cut method of the author, and his distribution for a dam of the indicated type.

The author mentions a typographical error in the original of the arch deflection formula of the late Mr. Shirreffs, relating to a trigonometric function of θ. The derivation of this formula, it is true, will result in the expression as written by the author in connection with

* Continued from October, 1914, *Proceedings*.

† New York City.

Mr. Brodie.

Fig. 6, but it was originally written, evidently, to retain the angle, θ, throughout, instead of involving 2 θ, as the author has written in the numerator of the first term of the expression for CC_c. That is, the last term of this numerator, $\frac{1}{2}$ (cos. 2 θ — 1) is equal to (cos. $^2\theta$ — 1), as originally expressed.

The author's Formulas (6) and (7) are open to some question, in the writer's mind.

The intensity of stress due to the weight of a large dam, reservoir empty, is not generally uniformly distributed in an up-and-down-stream direction, over the foundation, though for a thinner arch ring this uniformity of distribution may be approached. Furthermore, the initial axial stress (in terms of head of water) due to the weight of the dam, assuming for the time that its weight is uniformly distributed over the base or foundation, will, with Poisson's ratios taken at $\frac{1}{4}$, be as the author states, $\frac{1}{3} \times 1.27\ H$, where H is the height of the dam above the horizontal layer at the foundation level. Unyielding abutments are supposed to resist this axial strain; but the resulting strain in the horizontal direction at right angles to the axial strain, up and down stream, is opposed by the water pressure only on the up-stream side of the dam at the given level. Yet, with the water level at the top of the dam, a head of $\frac{1}{3}\ H$ is assumed to oppose this up-and-down-stream strain. The unrestrained down-stream side has been neglected in considering $\frac{1}{3}\ H$ as in Formula (6), by the author.

In other words, unless there be a force on the down-stream side, opposing the water pressure on the up-stream side, it is not clear to the writer how the initial axial stresses can be considered to resist the intensity of pressure due to a head of water, h, nor is it at all clear how this "resistance" can be so definitely determined, as stated in Formulas (6) and (7), with the above mentioned facts in mind.

In closing, the writer wishes to emphasize the thought expressed by the author that there is no single type of dam that may readily be applied to every site. Each site provides its own problem to be thoroughly investigated.

A METHOD OF DETERMINING STORM-WATER RUN-OFF.

Discussion.*

By Messrs. Samuel D. Bleich, Charles E. Gregory, and Samuel A. Greeley.

Mr. Bleich.

Samuel D. Bleich,† Esq. (by letter).—Mr. Buerger's new run-off formula again calls attention to the uncertainties and general confusion surrounding the technique for determining the run-off from the valuation of the numerous elements on which it depends. Almost every conceivable physical feature of a drainage area affects the run-off in some manner, but the relation of each can only be described qualitatively. These features have not as yet been adequately expressed mathematically.

Mr. Buerger gives a résumé of the various empirical formulas which have been proposed for the computation of run-off in terms of the salient characteristics of the drainage areas, such as size, general slope, relative imperviousness, and the length of the sewer. These formulas, it is claimed, are defective and give inconsistent results, as they were devised to fit local conditions. His objection to the so-called rational or "time element" method is that it is difficult of application; and he proposes his formula as its "acceptable equivalent."

The expression which Mr. Buerger gives for the run-off is necessarily complicated, as the rate of run-off per acre is made to depend implicitly on six elements or characteristics of the drainage area. In other empirical formulas, such as those by McMath, Bürkli-Ziegler, and others, the run-off is given explicitly in a simple relation, in terms of four elements only: area, slope, imperviousness of ground, and rainfall intensity. As a result of the complicated form of the proposed

* Continued from November, 1914, *Proceedings*.

† Asst. Div. Engr., in Chg. of Sewer Design, New York Public Service Commission, First Dist., New York City.

Mr. Bleich.

formula, three diagrams are required in solving it, whereas, for the other formulas, one is sufficient. It would be interesting to know how the form of the new formula was devised.

The rational method, as developed in actual practice, although not as simple as the standard empirical formulas, is neither more difficult nor much more time-consuming than the proposed formula. It appeals more to reason and, on account of its simplicity and directness, meets with general favor. It is true that it has its shortcomings, but so have all the empirical formulas, and probably to a greater degree. The empirical formula is involved, and the relations of the factors are obscure; in consequence, it is not expected that it will come into extensive use. Its advantage over the simple empirical formulas is not evident and, in addition, it involves certain inconsistencies which destroy its validity.

It is believed that Table 20 and Fig. 7 will facilitate the use of the Buerger formula. Table 20 contains computations of the values of N and P, and Fig. 7 solves the expression,

$$q + q^{\frac{4}{5}} N = P,$$

by a series of straight lines. With N and P obtained from Table 20, q may be obtained from the diagram, Fig. 7, at the intersection of these values for N and P.

It is generally conceded that the larger the drainage area, other conditions being equal, the smaller will be the run-off per unit of area. This is contradicted by Mr. Buerger's formula. Examining the expression for N it is seen that N decreases as A increases; and, from the expression for q, q increases as N decreases; therefore, q increases as A increases. It is conceivable that two slightly different areas, may have the same values for m, K, S, C, and L, and for these two areas Mr. Buerger's formula will give a larger run-off per acre for the larger area, which is contrary to experience. The increase of run-off per acre with increasing areas is not large, but being in the wrong direction, it militates against the validity of the proposed formula.

Mr. Buerger's formula, therefore, appears to be contrary to reason and experience in the relation which it involves between q and A; and in this respect it certainly has no advantage over the other empirical formulas which he mentions. McMath's formula is approximately consistent, and, by a proper selection of values for the two constants, C and R, it may be made to give satisfactory results. It certainly is easier to apply than the new formula.

In practice, the writer prefers the use of the rational or "time element" method, the results to be checked systematically by McMath's formula, with values for the constants suitably selected in both cases.

Mr. Bleich.

Notation:

q = run-off, in cubic feet per second per acre;
m = average slope of surface, to inlet, in feet per 1 000 ft.;
K = inches of rainfall per hour, for 1 hour;
A = area, in acres;
S = average slope of longest sewer, L, in feet per 1 000 ft.;
C = ratio of run-off to rainfall;
L = length of longest sewer, in feet.

Explanation:

P is obtained by multiplying Column 2 by $K\,C$.
Columns 3 and 4 give P for $K = 1.5$ and $K = 2$, for $C = 1$.
N = Column 5 × Column 7 × Column 9 × Column 11 × L.
With N and P known, q may be computed, or obtained from Fig. 7.

Mr. Gregory.

CHARLES E. GREGORY,* ASSOC. M. AM. SOC. C. E.—The author has not only felt that storm-water run-off formulas have been popular, but he has also felt, as have many others, that the results obtained have not always been reliable, and his aim has been to devise a formula which would be as reliable and as susceptible to adaptation to varying conditions as the so-called rational method.

In order to add to the reliability and adaptability of the formula presented, the author has introduced more factors than have been commonly used, and, in this case, it has resulted in a rather involved and difficult expression. The speaker believes that the rational method should be used for all important sewer designs, and does not advocate the use of any formula except where only approximate results are required, and where it is permissible to save time by the use of a simple formula in which the relative importance and significance of its coefficients are understood by the user. The formula presented by the author is not simple, and the relations of its parts have not been rationally explained.

The exponential formulas in common use are the simplest in form, but do not account for variation in the shape of the area drained, or the arrangement of the drains, and do not allow for variation in time for entry. The possible error in using these formulas, due to variation in shape, ranges from 15% in one direction to about 25% in the other, when compared with the average watershed.

The formula presented by Mr. Buerger contains a factor, L, for the greatest length of drain, and uses the factor, m, to indicate a slope of land surface to the sewer inlets. The other factors are included in the ordinary exponential formulas. The use of the factor, m, to allow for variation in the time for the water to reach the sewer inlets is not sufficient, as the slope is by no means the controlling influence in the time of entry. The length of run is of quite as much importance, and, in built-up sections, the type of roof collection, as brought out by the speaker in a discussion† of the paper by C. E. Grunsky, M. Am. Soc. C. E., entitled "The Sewer System of San Francisco, and a Solution of the Storm-Water Flow Problem", will have a greater influence than either slope or length of run. This variable could be represented much better by a simple time factor ascertained by a consideration of all the elements by which it is influenced.

The speaker, in his paper‡ entitled "Rainfall and Run-Off in Storm-Water Sewers", presented two formulas, one in the exponential form rationally deduced to show the relation of the various factors to each other and make possible a reasonable modification of the con-

* Mt. Kisco, N. Y.

Mr. Gregory.

stants, and one for use in connection with the rational method to get a first approximation. Under average conditions, this formula gives accurate results, as every factor in it may be directly modified to fit exactly all the assumptions which might be made in the rational method, except the expression for average velocity, which was necessarily based on average conditions, and is expressed in terms of area and average slope. The value of this average velocity, however, can be very easily and quickly tested and corrected, as soon as the first approximate result has been obtained, by using a Crane slide-rule, as modified by the speaker to give velocities directly. The basis of this formula is the ordinary rainfall intensity curve in the form:

$$I = \frac{B}{t + D}$$

in which I = the rate of rainfall, in inches per hour, B and D are empirical constants, and t = the duration of downfall, in minutes. In the original form used $B = 105$, $D = 15$, and $I = \frac{105}{t + 15}$. By changing the constants, B and D, this curve can be made to fit almost any rainfall curve desired. Assume that $t = \frac{L}{V}$, that L is the greatest length of drain, and V is the average velocity of flow; express V in terms of A and S, add to D a time for entry, in minutes; apply a coefficient, C; assume that inches per hour of rain are equivalent to cubic feet per second per acre, Q, and the rainfall curve becomes a rational run-off formula with all its elements easily understood and in a much simpler form than the one presented. If it is desired to use the intensity curve for New York City which gives intensities which will probably occur not oftener than once in 10 years, on an average, B will = 150 and D will = 15; allow 5 min. for the rain to reach the inlets, and the entire run-off formula for such assumptions will be as follows:

$$Q = C \frac{150}{\left[\frac{L}{84 \sqrt[5]{A S^2}} + 5\right] + 15}.$$

The coefficient, C, representing the ratio of rate of run-off to rainfall, in this or any of the exponential formulas, may be assumed to be influenced most by the percentage of imperviousness, as is done by Mr. Buerger where he says the theoretical range is from 0 to 1.00, corresponding with the imperviousness of the soil, but such an assumption will not give results even approximately in agreement with gaugings. His assumptions for what he calls "less unusual conditions" ranging from 5 to 50%, as a function of population, are more nearly correct for rain periods not longer than the time for concentration.

Mr. Gregory.

This factor, C, is not, as stated by the author, the ratio between the run-off and total rainfall, but is the ratio between the maximum rate of run-off and the average rate of rainfall for the time of concentration, and is governed by a combination of influences which may be shown in their relation by the following formula:

$$C = e\,(f\,g + (1 - f)\,h\,g) = e\,g\,(f\,(1 - h) + h);$$

e = coefficient of distribution which is a function of area;
f = percentage of impervious area;
g = ratio of run-off to rainfall due to storage on catchment surfaces and in the drainage structures; it is a function of t, and is influenced by the time for concentration and the relative area and character of the time zones;
h = ratio of run-off to rainfall due to perviousness of soil; it is a function of t and I.

The speaker, in a previous paper, deduced empirical values for C in terms of t. The value for C, as deduced from gaugings in the Sixth Avenue sewer in New York City, may be obtained by assigning values in the above formula as follows:

$$e = 0.9,\ f = 0.9,\ g = 0.5, \text{ and } h = 0.10;$$

then
$$C = 0.9 \times 0.5\ (0.9\ (1 - 0.10) + 0.10) = 0.41.$$

Additional data are being collected by the speaker, the better to establish values for e, g, and h. The factors, e and g, vary in opposite directions, tending to balance each other, and, for ordinary and similar conditions, a constant value for C may be used for maximum results without very serious error, after it has been established by giving due weight to its various factors. Assumed relations between population and impervious area should be used with great care, and should not be expected to give accurate results.

The use of diagrams to give results for various factors of a formula is to be commended, and the values of e, g, and h can be expressed much better in this way, as the law of variation for each changes at various points.

Studies have been made by the speaker to show the relation between the size of the sewer and the amount of damage done by flooding at various time intervals. Curves showing the relation between cost of sewers of various capacities, expressed in terms of frequency of flooding, to corresponding damage costs indicate that for certain cheap developments it would be more economical to have no sewer at all; though, at the other extreme of city development, similar to parts of the Borough of Manhattan, New York City, one flood would cost far more in damages than a sewer large enough to take the maximum storm. An important factor of sanitation is convenience and

Mr. Gregory.

suitability, which must be counted in favor of a sewer, or a larger sewer, and on this it is difficult to place a financial value. It is not wholly a problem of finance.

The curve given for New York on the diagram of maximum rates for 1 hour, Plate XIII, does not agree with data for the continuous 45-year record at the Arsenal in Central Park. This record gives values almost identical with the St. Louis curve shown on the same diagram.

In his discussion, Mr. Sherman gives Manhattan, New York City, as a place where the Hering formula is used. This is no longer true, as the rational method now prevails in that Borough.

Mr. Greeley.

SAMUEL A. GREELEY,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read with much interest this latest contribution to the important subject of storm-water run-off. The paper shows evidence of a large amount of work, as most of the available sewer gaugings are tabulated and checked by Mr. Buerger's formula.

The author has made a very fair statement of the various formula methods and the rational method for computing storm-water run-off in accordance with present practice, and it is his conclusion that the rational method has not received the widest use because it is laborious and requires a material exercise of judgment. This would indicate that two elements of value in the formula method are simplicity and speed of computation, and the elimination of the use of judgment. The writer agrees that the feature of chief value in that method is simplicity. He believes, however, that the exercise of judgment in the design of storm-water sewers should be promoted rather than discouraged. Even a formula computation will not give satisfactory results for any one locality, unless the user's judgment has been trained by experience in the use of the particular formula under existing local conditions. The Chicago run-off formulas computed by Mr. Hill,† are among the simplest in use and, with proper diagrams, permit of rapid computation. It appears to the writer that, in simplicity and rapidity, the proposed formula and the diagrams for its solution do not compare with some others now in use. It must stand, therefore, on its wider and more accurate application.

The formula proposed by Mr. Buerger, as shown in Equations 9, 10, and 11, is not a simple expression, and is not readily comprehended by engineers who have not had the opportunity to make special studies of formula derivation. The following comments, with reference to the units used in the formula, are submitted.

Coefficient, C.—It is not clear, from the definition given by the author, whether C is a ratio of the total volume of rainfall eventually reaching the sewers to the total rainfall, or the ratio of the maxi-

* Winnetka, Ill.

† *Journal*, Western Soc. of Engineers, October, 1902.

Mr. Greeley.

mum rate of run-off to the average rate of rainfall during the period of concentration to the sewer under consideration. The values of C, as determined in actual gaugings, represent the latter ratio.

Slope, S.—The author defines the factor, S, as the average slope of the longest sewer, L, in feet per 1 000 ft. It is not clear whether this means the composite average of a series of sewer lines at different slopes or the average slope of the sewer between two points, irrespective of breaks in the grade. The latter interpretation of this factor would simplify the computations.

Average Slope of Ground, m.—In his formula the author introduces a factor to represent the average slope of the ground surfaces to the sewer inlets. The writer's experience has been that this factor is difficult to ascertain accurately in practice. A large sewer area covering a broken surface will show considerable variation in the average slope at different points along the line. The relative weight of these different slopes in the general average is hard to determine. In the rational method this factor is accounted for in the time allowance for the flow of storm-water from roofs, yards, etc., to the sewer inlets. This time allowance is added to the time of concentration for the sewer, and is ordinarily not more than 15% of the total concentration period and is frequently less. Errors in the assumed time of entrance into the sewer are, therefore, of less relative importance.

Rainfall per Hour, K.—The author uses a rainfall factor equal to the expected rate, in inches per hour for a period of 1 hour, and recommends that sewers be designed to receive the run-off from rains of an intensity which may be exceeded once every year. The writer believes that this is too frequent a surcharge for many cases, and that in certain more critical conditions provision should be made for a higher rate of rainfall.

A comparison of the work required to determine the values of the factors entering into Mr. Buerger's formula with similar steps required in the rational method does not appear to the writer to favor the new formula. The coefficient in both cases must be selected with judgment. In the Buerger formula, it is necessary to determine the length of the longest sewer run and its average slope. With these factors determined, it is not difficult to estimate the average velocity and resulting time of flow in the sewers. The factor, m, required in the Buerger formula is, in the writer's judgment, difficult to determine with accuracy, and is not as easy to apply as the constant time factor used with the rational method for the flow time of storm-water to the sewer inlet. The rainfall factor, K, in the Buerger formula, will be constant for any one vicinity, and, therefore, the selection of varying rates of rainfall corresponding to different times of concentration is eliminated.

Mr. Greeley.

The writer has recently designed a system of storm-water sewers for a town in the West having a population of about 5 000. The town was divided into three storm-sewer districts. A ridge about 40 ft. high runs through these districts near the center, separating two flat areas, a lower and an upper. In one of these districts it was necessary, in order to avoid excessive cuts, to carry the main sewer around the end of the ridge. On this account the length of sewer run and the time of concentration for District B were considerably greater than those for District A, although the two districts were not very different in area. The writer made the computations for storm-water run-off in accordance with the rational method and also with Mr. Hill's modified Bürkli-Ziegler formula. The coefficient used with the rational method was determined from a series of gaugings made on the combined sewers now used in the town, in accordance with Table 21, so that a very fair determination of this factor was possible. Since making these computations, the writer has computed the storm-water run-off by the Buerger formula, and was interested to find that the results compared very favorably with the determinations according to the rational method. In both computations, the smaller run-off was estimated for the larger area on account of the longer time of concentration. The results of these computations are shown in Table 22. In thus using the Buerger formula, the writer found it difficult to make an accurate estimate of the value of m, therefore he made two computations, using different values of m.

TABLE 21.—GAUGINGS IN CHERRY STREET SEWER, WINNETKA, ILL.

Date, 1912.	Time before maximum discharge, in minutes.	Area tributary in this time, in acres.	Inches per hour.	Cubic feet per second.	Maximum flow in sewer in excess of dry-weather flow.	C.	Remarks.
July 20th.....	75	381	0.163	62.1	13.5	21.7	Sudden moderate shower.
July 20th.....	50	320	0.200	64.0	15.0	23.4	12 hours after previous storm.
July 23d.....	25	160	0.450	73.9	15.5	20.9	Short, sharp shower.
July 28th.....	60	365	0.154	56.2	12.3	21.8	Second of two showers.
August 8th.....	30	195	0.390	76.8	11.7	15.2	Short, quick storm.
August 9th.....	75	381	0.22	82.3	13.0	15.8	8 hours after previous storm.
November 12th..	20	130	0.90	116.8	20.2	17.3	Sharp, short shower.

There is one point about Mr. Buerger's paper which deserves comment. He has tabulated most of the recorded gaugings of storm flows in sewers, and has compared these gaugings with results computed by his formula method. It would appear that the formula method should give the maximum run-off to be expected from the local conditions of each gauging. The gaugings, however, do not show maximum run-offs, but, in many cases, figures which are considerably below

the maximum run-off. The comparison should be judged with this fact in mind. Mr. Greeley.

K = Rate of rainfall, in inches per hour	0.9	0.9	0.9	0.9	1.2	0.95	1.0	1.0
S = Average slope of sewer, L, per thousand	7.8	5.2	7.8	5.2	7.8	5.2	.....	.....
m = Average slope of ground, per thousand	7.0	5.0	2.0	1.0	.....	.....	.....	.....
T = Time of concentration, in minutes	.....	.....	.....	.....	33	50	.....	.....
P	0.5	0.45	0.4	0.35	.....	.....	.....	.....
N	0.5	0.9	0.4	0.75	.....	.....	.....	.....
Q = Total run-off, in cubic feet per second	48.0	36.0	41.6	30.6	38.5	34.2	24.0	25.2

In conclusion, the writer finds that this formula gives satisfactorily accurate results as compared with the rational method for the particular application made, but he does not consider it easier to use, and he does not favor attempts to reduce the exercise of judgment in storm-sewer design. The value of m is not easily determined. It would seem to him that engineers should attempt to secure data and gaugings which could be used as guides for judgment, rather than to reduce the importance of the judgment factor. The author's discussion of run-off has added materially to the data on that subject, and his suggestions as to the frequency of surcharge and the general similarity of rainfall intensities over comparatively wide areas, have simplified the selection of rainfall rates in storm-sewer design, and thus have made easier the exercise of judgment along this line.

THE DESIGN AND CONSTRUCTION OF FOUR REINFORCED CONCRETE VIADUCTS AT FORT WORTH, TEXAS.

Discussion.*

By Carl Gayler, M. Am. Soc. C. E.

Mr. Gayler.

Carl Gayler,† M. Am. Soc. C. E. (by letter).—It is not often that important structures such as these concrete viaducts are described as fully and clearly as in this paper. Publications of this kind are of great value to the Profession.

Reinforced concrete viaducts of the general layout and appearance of the four Fort Worth viaducts are not uncommon, but the construction of arches by using steel centers embedded in the concrete of the arches and forming an integral part of them is of recent date.

At first glance, comparison with the Melan arch suggests itself; there are, however, the following radical differences between the two systems:

1. The steel ribs of the Melan arch are not designed to be self-sustaining over the full length of the span under the weight of the concrete of the arch proper.

2. The usual assumption for the computation of Melan arches—that the concrete resists the direct thrust and the steel ribs take up the bending moment—is, considering the distance between the steel ribs, open to criticism. On the other hand, the suppositions under which the arches of the Fort Worth viaducts were calculated are definite and logical, and may be summarized as follows: The steel ribs alone carry, in the first stage of the work, their own weight, that

* This discussion (of the paper by S. W. Bowen, M. Am. Soc. C. E., published in August, 1914, *Proceedings*, and presented at the meeting of December 2d, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

† St. Louis, Mo.

Mr. Gayler.

of the concrete as it is being poured into the forms around them, and that of the lateral braces. The stresses thus produced in the steelwork can be accurately ascertained; the concrete is merely dead weight, and the question of the difference of the moduli of elasticity of the two materials is not involved. The final stresses in the arch ribs resulting from the additional weight of the superstructure, and from the live loads, are provided for as in other reinforced concrete arches, the steelwork of the ribs forming part of the steel reinforcement, as fully explained by Mr. Bowen.

3. The distribution of the metal through the body of the concrete in the ribs of the Fort Worth arches is far superior to that in any Melan arch ever built.

After careful consideration of the problem with which the consulting engineers had to deal, that is, to build, safely and economically, the arches of the vidaucts under the difficult conditions of a limited clearance, the probability of sudden and extraordinary floods, and an unstable river bed, the writer is convinced that the plan adopted was the one logical solution of the problem. Under analogous conditions, it will undoubtedly be repeated.

The conclusion, however, which Mr. Bowen has reached, that "for high structures, and for those over streams subject to sudden and great variation of water level, this method is cheaper and safer than to use falsework supported from the bed of the stream", needs modification, inasmuch as, in the case of high structures, this method has to compete, not so much with ordinary falsework, as with steel centers placed below the concrete.

Where the height of the arch above the high-water line admits of the use of "free" centers, that is, centers under the concrete, the latter method, in most cases, will be found to be the more economical.

In the first place, the height of the steel centers is then independent of the thickness of the concrete arches or arch ribs, and great saving in the weight of the steel, especially in long spans, can be obtained by choosing an economical height for the steel trusses or arches.

It is also feasible to get along with a set of centers for one (longitudinal) half of the arch only, and to utilize this set again for the other half. On a number of concrete viaducts great saving in the cost of erection has been obtained in thus using the falsework or centering over again, as for instance, on the great viaduct built a few years ago in the Duchy of Luxemburg, on the Walnut Lane Bridge, at Philadelphia, Pa., the Rock River Bridge, at Cleveland, Ohio, and the Kings Highway Viaduct, at St. Louis, Mo. Even the scrap value of the free centers is an item worth taking into account.

The saving in steel gained by utilizing the steel ribs as reinforcement of the arch will thus in most cases be greatly overbalanced if free centers are used. The arches of numerous concrete viaducts

Mr. Gayler.

have been proportioned so that bending moments were practically eliminated and, of course, in all such cases no strengthening of the arch by the embedded steel ribs would be claimed.

Another advantage of free centers is that they are applicable to the circular as well as to the ribbed arch. The method used on the Fort Worth arches, except for short spans, is probably limited to the ribbed arch, on account of its greater available thickness.

An excellent illustration of the advantages of free centers over embedded centers, in the case of a high structure, is found in the successful erection of the Rock River Bridge, at Cleveland, Ohio, by three-hinged steel centers, designed by Wilbur J. Watson, M. Am. Soc. C. E.*

Mr. Bowen states that the object of his paper is "to bring out a discussion of the type of reinforced concrete arch in which the reinforcement is composed of structural shapes and is designed to support the weight of the forms of plastic concrete in the arch ring on ribs", but a few remarks on other features of the viaducts may be allowed.

In looking over the foundations of the piers, as shown on Plates XV, XVI, and XVII, an impression was left on the writer's mind that the old conflict between the sincere endeavor of the engineer to obtain the best results and the barrier set up by a limited appropriation has not been decided fully in favor of the engineer, as far as the question of foundations of the piers of the Fort Worth bridges is concerned. This is written with considerable diffidence, because a thorough acquaintance with the nature of the material in the river bed alone could justify criticism. The following points, therefore, are brought out merely as suggestions, and will be touched on as briefly as possible.

The footings of a number of the piers in the bed of the river, that is, inside of the levee protections, for instance, Pier 3 of the Main Street Viaduct, the piers of the Seventh Street Viaduct with the exception of Nos. 1 and 2, and some of the piers of the East Fourth Street Viaduct, are not carried down as deep as the river bed. For their protection against scouring, rip-rapping is relied on, which may, or may not, be properly renewed in years to come.

The base of Pier 2 of the West Seventh Street Viaduct, judging by the small-scale elevation on Plate XV, seems so provokingly close to rock that it may not be unreasonable to ask why this chance to obtain an unyielding foundation on both sides of a rather flat concrete arch was not utilized.

Even the problem of a solid foundation for Pier 2 of the Main Street Viaduct, carefully as it seems to have been studied by the consulting engineers, leaves some doubt in the mind whether rock might not have been reached at a reasonable price. According to Plates XV

* *Transactions*, Am. Soc. C. E., Vol. LXXIV, p. 1.

Mr. Gayler.

and XVII, the 15-ft. oak piles at the north side of the pier reach down to within a few feet of it.

As to the design of the bearings of the track rails, adopted for reasons of economy, it is not likely to be repeated on other viaducts. The life of the fiber pad, ½ in. thick, which is to act as a shock absorber, will not be a long one, and the hammering of the wheels under the electric railway traffic will then be a serious matter for the slabs and girders.

In speaking of the advantages of the three-hinged, ribbed arch, it was an oversight on Mr. Bowen's part to claim that water-proofing is, in every case, a necessity for the circular arch; but, aside from this, every word he has said is true, and should be welcomed by every structural engineer. Concrete arches should either be built with hinges or efficiently reinforced against temperature stresses. Too long, for the credit of the Profession, have concrete arches been built in the United States with disregard for temperature stresses or under assumptions of changes of temperature which, on their face, are not true.

Changes of temperature in the body of concrete arches produced by long-continued heat or cold can be ascertained, either by judgment confirmed by experience, or by actual tests on existing structures. Whenever excessive stresses result from such changes, hinges should be used.

As the writer expressed it in a previous publication: This (that is, the assumption of inadequate changes of temperature in order to obtain convenient stresses in the arch) is the only instance on record in the history of engineering where an attempt is made to adjust the laws of Nature to the works of man, instead of *vice versa*.

It is true that in former years the three-hinged steel arch had gradually to give way to the two-hinged or to the fixed arch, on account of its lack of rigidity under moving loads, but with the heavy concrete arch this defect is, to a great extent, overcome, and should not be a serious objection to the use of the center hinge.

THE CLARIFICATION OF SEWAGE BY FINE SCREENS.

Discussion.*

By Messrs. Rudolph Hering, J. H. Granbery, Langdon Pearse, L. C. Whittemore, Samuel A. Greeley, and E. Kuichling.

Mr. Hering.

Rudolph Hering,† M. Am. Soc. C. E.—The author has given the most complete description of apparatus for screening sewage that is published to date. Heretofore, the best description was by Dr. William P. Dunbar,‡ but, being a physician and a sanitarian, he does not enter fully into the engineering features. Therefore Mr. Allen's account of these features of practically all the screens that have been used for the treatment of sewage is welcome.

The speaker has only one criticism to make, and that relates to the title of the paper: "Clarification of Sewage by Fine Screens". Screens do not clarify sewage at all. Even the finest screens do not remove turbidity, and a turbid sewage is not one that has been clarified.

Screens are used for the purpose of, and are of most value for, retaining floating matter. Floating matter may clog pipes or pumps, and it usually makes the surface of watercourses, into which it may be discharged, offensive.

There are in use a number of different designs, which have originated mostly in Germany. Almost every conceivable arrangement has been tried there. Most of the screens are apparently satisfactory; each engineer usually prefers his own. All have some advantages over others, and an outsider, who takes a general point of view, can usually determine the specific conditions which are best suited for one or the other design. The author has done this, and has given his general conclusions.

* Continued from November, 1914, *Proceedings*.

† New York City.

‡ "Principles of Sewage Treatment;" First Edition, Translated by H. T. Calvert, Lond., 1908.

Mr. Hering.

The general conclusions which the speaker has drawn from his study of screens, are substantially as follows: Screens which are to be used before the sewage reaches pumps may be quite coarse; they may be bar screens. It would be throwing away money to use a fine screen, like that of the Riensch-Wurl type, before a pump and for no other purpose, because a pump, and particularly a centrifugal pump, will pass very large solid matter without objection.

Coarse screens are also sufficient for any sewage treatment, when the sewage first goes into tanks where it is supposed to be detained. Fine screens are unnecessary in this case because coarse matter may remain in the tank. The heavy matter will settle to the bottom and the light matter will stay on top. Light matter can be removed much more thoroughly and cheaply from a tank than from a screen.

Fine screens have a different purpose than coarse screens and, therefore, a different line of application. A fine screen is needed when the raw sewage is to go out into a river. A coarse screen would not be satisfactory, because it does not prevent floating matter, visible on the surface of the water, from passing out. Take the case of New York Harbor, or along any river, large or small. If the sewage is to receive no other treatment than screening, a fine screen is necessary.

Fine screens are also desirable if the sewage is to be put through sprinkling filters, or if it is to be turned upon sand filters. By passing sewage first through the fine screens, a much greater quantity can be put on each acre, for oxidation, than is otherwise possible before clogging will result.

Parenthetically, it may be added that in some of these sewage filters even the finest screens may not prevent clogging. The speaker has pulled out from under sprinkler nozzles spreading sewage over a bed, lumps of matter, mycelium and other fungous growths, almost as large as one's fist; and yet the sewage had been fine-screened. Of course, the fungus had grown to large size where it was found, and plants will grow large, even in the sewage beds themselves. Screens do not prevent clogging from such causes, nor will they stop grease from accumulating on and obstructing the beds.

The speaker thinks that in the future there may be another application for fine screens not found in use at present. It refers to the removal of suspended matter before the sewage reaches an outfall. Quite a number of years ago the speaker was shown a result in England which then astonished him. Dr. Travis, in Hampton, having taken some sewage out of a sewer, passed it through filter paper, which made it perfectly clear. He said that this sewage was, not only clear, but on standing it would not get foul. He showed the speaker samples which had been standing for weeks and months, and they had no odor.

Mr. Hering.

The speaker has found the same result in American cities. If you take sewage, as it leaves a house or soon after, and filter out all the suspended matter—in other words, get a clear solution—it very rarely becomes foul on standing.

When sewage leaves the house, nearly all matter which becomes foul is in a solid or colloidal form. There is very little organic matter in solution: a little urine and a little of the animal and vegetable juices in the kitchen waste water will be about all. The great volume of the liquid leaving the house is water. The speaker has had sewage analyzed as it leaves the house and has found that the organic matter, the only matter with which we are concerned here, is nearly all in a suspended condition.

Now, as the sewage travels down the sewer this solid matter is broken up, comminuted, and dissolved, and the liquids leave the animal and vegetable cells, so that, at quite a distance down the sewer, one will find a large quantity of organic matter in solution. The figures that Mr. Allen has given in the tables were obtained by various authorities, and usually give the results at the mouths of the sewers. The speaker has thought that the authorities ought to add how far the sample was taken from the average point of sewage origin, because the farther the sewage flows the more organic matter it will hold in solution.

In the future, as our population increases, there is going to be more trouble or expense than now in treating sewage to obtain higher standards. It may then become more expensive than now to oxidize the stronger solutions of organic matter below the sewage outfalls. It may then be necessary to remove the suspended matter higher up and as near to its origin as practicable, because much of the organic matter which soon dissolves cannot be treated as economically in liquid as in its previous solid form.

Take, for instance, a case like the Passaic Valley Sewer, near New York City. The main sewer is more than 20 miles long. When the sewage of Paterson, at the upper end, gets to the lower end of the trunk sewer, at the pumping station, fine screening is superfluous. There is almost nothing left to screen out except the very coarse and slowly soluble matter which has come down that great distance and must be taken out simply to protect the pumps. Most of the organic matter is churned up and comminuted. It is the same as at the outfalls of the longest sewers in London, Berlin, or Paris. Most of the organic matter which could have been taken out before is still there, but is so finely comminuted that screens cannot remove it.

The speaker believes that where sewage is disposed of by dilution, a removal of the suspended matter nearer the origin may often be economical, and may increase the diluting capacity of the stream.

Mr. Hering.

Besides screening, there is one other way in which one can quickly get most of the suspended matter out of sewage, and that is by settling basins. It is known that more suspended matter can be taken out of sewage by sedimentation than even by the usual method of fine-screening. This may not always be true, however, if the screening is done early, when more screenable matter is floating, than later. Usually, the preference between screening and settling, and the best locations for treatment, will be determined by the question of relative cost for the advantages gained.

The speaker believes, as the author has argued, that the question of screening and its relative advantages should be studied a little more thoroughly than has been done heretofore.

Mr. Granbery.

J. H. GRANBERY,* M. AM. SOC. C. E. (by letter).—The screening methods in the Paris sewers may be of interest. The process has been in use there for some time—since 1867, according to Mr. M. Ducat, Assistant Engineer, *Bureau des Eaux et des Egouts*. With the exception of changes of motive power, and improvements in mechanical details, the apparatus is practically the same as then installed, and has been giving satisfactory results.

The sewers of Paris are of such large cross-section that the screening is carried on in the sewer itself, and as a consequence the material is fresh, and the odor is no more objectionable than that of any underground passage. It is not unlike the odor of the New York subway on a wet day.

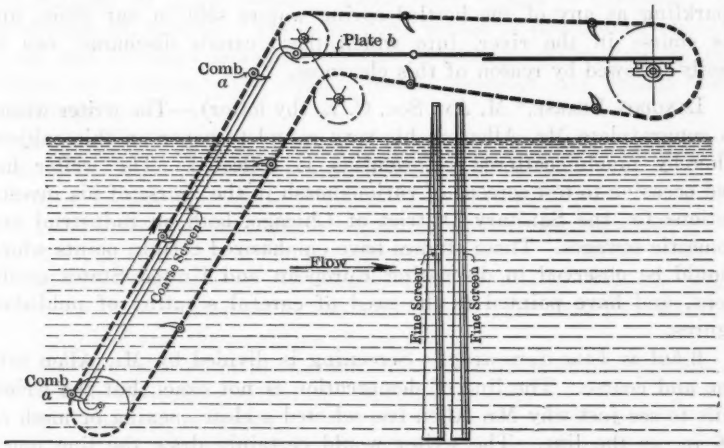
The screening is done in certain portions of the sewers, which have rectangular channels provided for this purpose, and consists of both coarse and fine screening. The device is shown diagrammatically by Fig. 30, and consists of a coarse screen composed of inclined bars about ½ in. apart, followed by one or two finer screens which are removable. A series of comb-like bars (*a*, Fig. 30), having toothed parts which project between the bars of the coarse screen, are drawn upward mechanically, collect the coarse screenings, and drop them on a delivery plate, *b*.

Portions which adhere to the combs may be swept off on to the plate by the operator before the combs again enter the channel. Nearly all the coarse suspended material is at or near the top of the liquid mass. The finer material, which is more evenly distributed, and the material which passes the coarse screen, are caught by one of the fine screens. These are used singly, but the second one is lowered preparatory to removing the one in position, when the latter is to be cleaned. The fine screens are withdrawn and cleaned by hand above the channel.

The apparatus is mounted on a car which is driven by electricity, and the whole is moved against the current while the screening is

* New York City.

being done. This car can pull a trailer which carries a hydraulic press. The latter is used for baling the screenings, which are then taken to the "quai" (or to the railroad yards), whence they are shipped to the agricultural districts and used for fertilizer, or to low land that requires filling in. The Quai de la Megisserie, on the Seine, is one of these loading stations, and the sewer which parallels it has a wide channel in which boats are operated. These boats may be used to transfer the baled screenings along the "quais". Mr. Granbery.



COARSE AND FINE SCREENS USED IN PARIS SEWERS

FIG. 30.

The channels are normally filled to within a foot of the floor, on which carts may be used in certain portions, and this floor opens on the "quai" (in the case referred to) through openings protected by steel doors. These doors have been provided since the "inundation", and are arranged to prevent the water of the Seine from backing up into the sewers, which had caused considerable trouble at that time.

These works are in the heart of Paris, and do not cause any nuisance. There is no surface indication of their presence, and one may pass the loading stations day after day for weeks without becoming aware that the traffic carried is sewage.

The liquid, after screening, is not discharged into the river, as might be supposed, but is pumped under it and discharged by gravity through closed conduits to the agricultural park at Acheres, from 25 to 40 miles distant.

In the park the underground conduits have branches which discharge, through valves operated from the surface by hand, into open

Mr. Granbery.

main ditches, and thence into laterals which are spaced and located to suit the particular crop grown. The liquid discharged has the characteristic whitish color and appearance of dirty dishwater, and an odor that is offensive at the point of discharge but not noticeable 10 ft. from it. The flow in these open ditches is controlled by sluices.

The soil acts as a filter, and the plant growth seems to absorb all deleterious matter, for the soil does not seem to become foul. The filtered liquid is collected by a series of underground drains and open canals and is claimed to be potable. It is certainly as clear and sparkling as any of the bottled spring waters sold in our cities, and its course in the river, into which these canals discharge, can be easily followed by reason of this clearness.

Mr. Pearse.

LANGDON PEARSE,* M. AM. SOC. C. E. (by letter).—The writer wishes to congratulate Mr. Allen on his very complete paper on this subject, whereby much scattered information is collected. The writer has had occasion to test screens of various mesh in the course of his investigations for the Sanitary District of Chicago, both on industrial and domestic sewages. These studies have emphasized certain points which should be observed in discussing European and United States conditions, and have pointed to the need of careful scrutiny of published figures.

What is Fine-Screening?—Screening is divided by Mr. Allen into fine and coarse. The line of demarcation is not exact, but the writer fails to see just why Mr. Allen has selected a clear opening or mesh of 0.6 in. as the line. The writer would certainly draw the line much lower, certainly at or below 0.1 in., in the light of his experiments, as well as those of Monti (quoted in the paper). Screens on small pumping stations designed for automatic service are made with about $\frac{5}{8}$ in. clear opening, and pass most of the fecal matter in American sewages, retaining only rags or coarse non-friable material.

Methods of Analysis.—The writer has long felt that the present methods of studying sewages, from a mechanical standpoint, are not complete. Chemical analyses show nothing of the size of the particles contained therein, and but little of the true strength of a sewage. Biochemical analyses, studying the dissolved oxygen consumption, give truer indications of the real or absolute strength. The mechanical indications would best be given by screening, using screens of different mesh, perhaps in a nest, like sand sieves. The data presented by Mr. Allen on the results of screening show a concordance of results with different mesh which perhaps can be explained if the character of each sewage is defined. Comparative removal by meshes of different sizes must be studied on one and the same sewage, to be conclusive.

* Chicago, Ill.

Mr. Pearse.

Even then it is not always easy to obtain a uniform sewage. Again, samples of both raw and screened sewage must be collected frequently, and averaged for definite periods. Correct sampling, particularly of the crude sewage, is often difficult. The writer has concluded that the best method is to collect samples of both influent and effluent and weigh all the screenings, determining the percentage of moisture. Then the dry material caught is calculated in parts per million and added to the content of suspended matter in the screened sewage to ascertain the quantity of crude sewage. From these figures is calculated the percentage of removal. The suspended matter is determined on both crude and screened sewage—and the percentage of removal is calculated as a check. The former results, however, are usually more consistent.

Screen Factors.—The removal of suspended matter by screening is a complex function having many variables. It depends on:

1.—The size and shape of the mesh or screen;
2.—The loss of head under which the screens are operated;
3.—The character of the suspended matter;
4.—The freshness of the sewage, which in one of domestic origin will be influenced by the area sewered, the time of concentration, and the condition of the sewers;
5.—The dilution of the sewage; *i. e.*, the gallons of flow per capita, or the concentration of suspended matter;
6.—The type of screen.

In the writer's opinion, Table 12 would be increased in value many fold if columns were added giving (1) the area tributary to the screens; (2) the concentration of population per acre; (3) the concentration time of the sewage; (4) the flow, in gallons per capita; (5) the minimum and maximum opening, in inches; (6) the percentage of gross area which is opening; and (7) the content of suspended matter, in parts per million.

Foreign vs. American Sewage.—The great difference in American and European conditions might be shown by the foregoing data, particularly by the suspended matter content. For instance, by referring to Table 10, it will be seen that the Dresden sewage contains 371 parts per million of suspended matter. Many American sewages are more dilute. Industrial wastes are often more concentrated. As a rule, tannery, stockyards, and Packingtown wastes around Chicago seldom exceed 7 500 parts per million, and are usually greater than 500 parts per million. Domestic sewages in the United States seldom exceed 250 parts per million. The average suspended matter at the Thirty-ninth Street Pumping Station during 3 years has been 144 parts per million, from daily samples of twenty-four portions.

Mr. Pearse.

Dr. William Philipps Dunbar* gives the following characteristics of German sewages:

Place.	Suspended matter, in parts per million.	Free ammonia as NH_3.
Hamburg	299.4	27.5
Frankfurt	1 390	31.5
Wiesbaden	74	37

The writer does not believe that Mr. Allen has cited sufficient American data to maintain that the efficiency of fine-screening is equivalent to settling, particularly if fine-screening be defined as 0.6 in. or less for the clear net opening. Of the results given in Table 12, all but three are foreign data, on conditions possibly widely different from those obtaining in the United States. Of the three results in the United States, the Jennings screen is on a peculiar sewage, direct from the stockyard pens, containing much manure, hay, straw, etc. The average content of suspended matter is 340 parts per million. On tests made by the Sanitary District, a removal of 33% was obtained (based on "computed" influent). A 12-hour period of settling removed 64 per cent. Of the other two places quoted, Reading and Brockton, the results at Reading are placed much lower by George W. Fuller, M. Am. Soc. C. E.,† where 15 to 20% removal is noted, instead of 42% as in Table 12. This discrepancy is discussed in the following paragraph more at length.

At Brockton a very concentrated sewage is handled from a separate system. The data in Table 7 are quite inconsistent with the text which follows. From Table 7 the removal of suspended solids is 983 — 282 = 701 parts per million. From the text, in the same interval, 1.4 tons of screenings per million gallons were removed, or 336 parts per million, if the 1.4 tons is dry weight. This would give an efficiency of 54% removal instead of 71.3 per cent. If the weight is wet, the percentage would be much lower. Probably both figures are too high. It would be of interest if Mr. Allen would state the source of the analyses, and explain whether they are more than an average of twelve samples, collected during a few minutes once a month. Judging from reports of the Massachusetts State Board of Health, a removal of 983 parts per million of suspended matter does not represent average conditions, but is extremely high. In 1911, the yearly average was reported as 363 parts per million.

Reading Screen.—The data quoted from Emil Kuichling, M. Am. Soc. C. E., and from "Sewage Sludge" by Elsner, Spillner, and Allen, are not consistent. Mr. Kuichling estimates the dried matter at 750

* "Principles of Sewage Treatment," First Edition, Translated by H. T. Calvert, p. 34.

† "Sewage Disposal," p. 381.

lb. per million gallons, or 90 parts per million, giving an efficiency of 42% on a sewage containing a total of 215 parts per million of suspended matter. Mr. Allen's figures agree with a statement on page 77 of the Annual Report of the City Engineer of Reading (1910), where 31 cu. ft. per million gallons of screenings were obtained with 90% moisture. Taking the weight at 63 lb. per cu. ft.,* 1 953 lb. of wet screenings would be recovered, or 195 lb. of dry screenings per million gallons. This would be equivalent to 23.4 parts per million. Even on a weight of 70 lb. per cu. ft. the equivalent removal is only 26 parts per million. From the City Engineer's report for 1909, the suspended matter in the screened sewage appears to average 151 parts per million. Hence the screening efficiency is $\frac{26}{177}$, or about 14.7 per cent. Mr. Pearse.

The Reading screen was out of service the equivalent of 63 days in 1910, and 77 days in 1911. This would point to the need of duplicate installations.

Scrutiny of Published Data.—It is evident, from a comparison of the data quoted regarding the three American plants, that the efficiencies of screens are probably lower than Mr. Allen's figures. More detailed figures are needed on long-continued tests in order to establish the true figures. If a settling basin is to be rated by its average accomplishment, so should a screen. The writer, therefore, thinks that Mr. Jennings' figure of 63%, based on a peak load, is not a fair one to compare with an average load on a settling basin.

Other Types.—Although not strictly for sewage, two classes of screens may be added, to make Mr. Allen's references complete. One is the rotary or drum screen devised by the United States Reclamation Service.† This was for the purpose of removing trash from an irrigation channel on the Salt River project, and was provided with ½-in. mesh. The other is the type of machinery known in the paper trade as save-alls. These were devised to retain particles of pulp, paper, etc., which would otherwise be carried into a stream or sewer with the wash-water. They are largely of the drum type, fed inside, like the Weand screen, but are sometimes built so that the flow is from the outside inward. Cylindrical screens of this type have been in operation for nearly 20 years. Meshes as fine as 100 per lin. in. are used. They are cleaned by water or by air.

Comparative Tests.—Comparative screening tests on the Thirty-ninth Street sewage are shown by Figs. 31 and 32. This is a domestic sewage, very dilute, containing about 140 parts per million of suspended matter, from a drainage area of 22 sq. miles, with a concentration time of about 5 hours. The dry flow is roughly 200 gal.

* "Sewage Sludge," p. 208.

† Described in *Transactions*, Am. Soc. C. E., Vol. LX, pp. 337-338.

Mr. Pearse.

per capita. The population tributary in 1910 was 274 000, or 19.1 per acre. The tests were all made to a constant loss of head of 0.5 ft. on wire mesh screens, 4.2 sq. ft. in area, having the mechanical characteristics stated in Table 23.

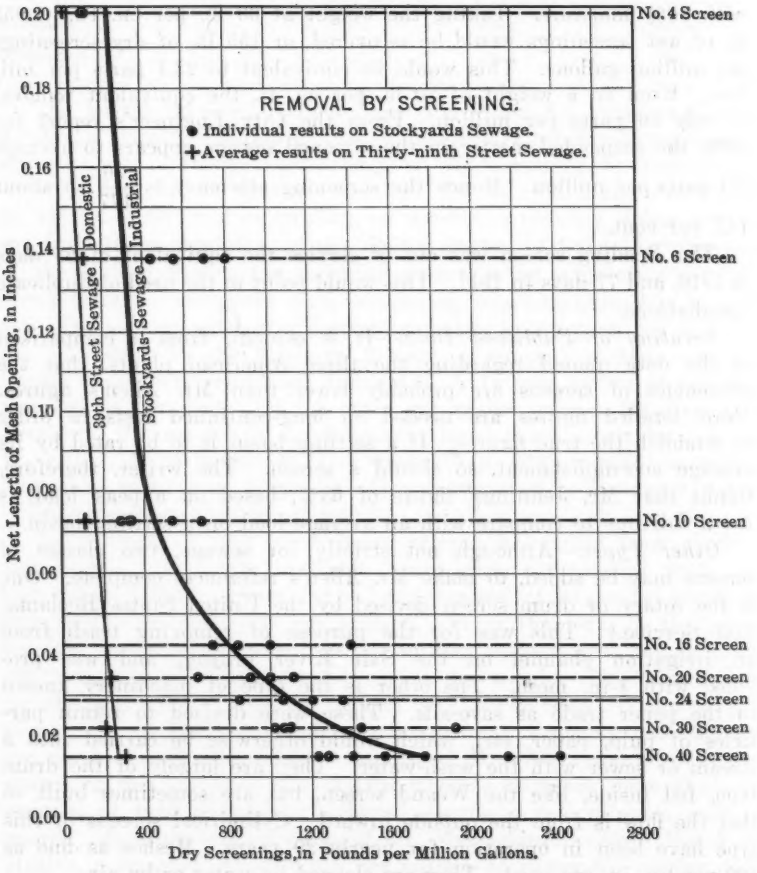


FIG. 31.

Screening tests made with screens of the same mesh, on the Center Avenue sewage, give the results noted by Fig. 31. These were made with a loss of head of 4.5 ft. on a 21 by 24-in. screen. The Center Avenue sewage contains much stockyards and Packingtown waste, with quantities of coarse material, such as paunch manure, hay, particles of meat, hair, etc. The drainage area is 660 acres, with a con-

centration time of about 30 min., a day flow of 700 gal. per capita (29.0 cu. ft. per sec.), and a night flow of 400 gal. per capita (16.4 cu. ft. per sec.). The removal is far higher than at Thirty-ninth Street. Mr. Pearse.

Effect on Organic Content.—The writer has been much interested in the data presented relative to the effect of screening on the organic content of sewage, as this problem has been studied by the Sanitary District from the standpoint of the biological oxygen consumed. The results quoted from G. M. Wisner, M. Am. Soc. C. E., were determined several years ago by the methylene blue method on a sewage now found to have a biological oxygen consumption of 100 to 150 parts per million. Recent extended tests on the improvement made by a 30-mesh Weand type of screen on the Center Avenue sewage, with a biological oxygen consumption of 1 100 parts per million, show an improvement of only 6%, with a removal of 8% of suspended matter, from a sewage containing about 487 parts per million of suspended matter. Settling the screened sewage removed 283 parts per million of the suspended matter, making a total removal of 66% on the crude sewage, with a reduction in oxygen demand of 42% in a number of tests. This certainly does not indicate that screening is comparable to sedimentation.

Recovery.—The screenings from the rotary screens, on a packing-house and on the Center Avenue sewer, averaged 84.3 and 86.4% of moisture, respectively, as compared with 91.5% of moisture in the sludge from an experimental Emscher tank 17 ft. deep. The organic content was high, but the fat content was not great, largely because the fats are in a finely divided emulsion, and require chilling before congelation and rising to the surface. The writer is not very confident in general of obtaining valuable recoveries from domestic sewage. Doubtless, too, the material would be open to the criticism that the foreign material, rags, etc., in the screenings would create suspicion in the mind of a farmer purchasing it as a fertilizer.

Mr. Pearse.

Cleaning.—The writer has always favored the use of compressed air instead of water for cleaning rotary screens of the drum type. In a screen tested in Packingtown, of a partly submerged drum type, so much water was used that a settling basin had to be built to settle the screenings. With the Jennings screen, the heavy air pres-

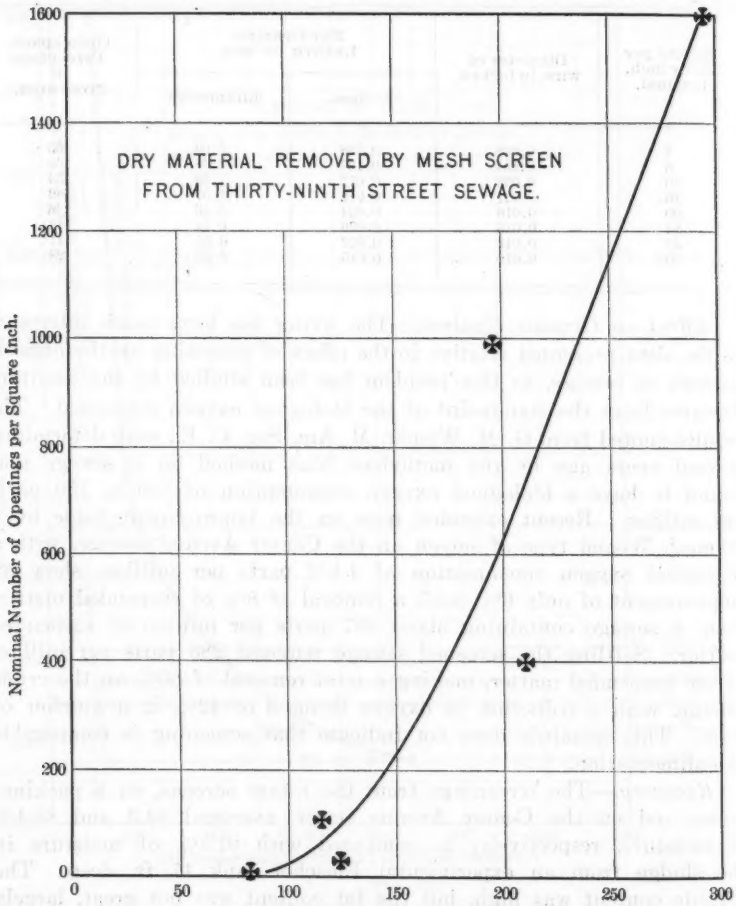

FIG. 32.

sures first used were too severe for the screen fabric, but later reduced pressures have appeared favorable. The cleaning must be adequate to keep down the loss of head or clogging of the screen below defined limits; little is gained in removal after a screen once begins to clog, as the rate of clogging increases rapidly.

Mr. Pearse.

Disintegration.—Mr. Allen refers to the disintegration of solids, with consequent passing through a screen. This would appear to be dependent on their character. Non-friable materials certainly would not break down. Further investigation is required. If pumping is needed, the disintegration produced thereby will probably exceed that caused by the screen. The writer has heard comment by other observers on this point, but would judge that that condition, particularly with the Riensch-Wurl type, is not continuous.

Mechanical Details.—The Weand screen requires considerable loss of head, and consequent pumping cost, in many localities. The Riensch-Wurl and other partly submerged foreign types require but slight loss of head, compared with the Weand.

Of the screens now in use in America, some mechanical improvement is required to put them in a permanent class. The screen at Reading may have been experimental, but it required costly repairs. The screen at Brockton has had some difficulties, as outlined by Mr. Allen. Foreign practice has developed certain types of screens which appear to have been operated with slight mechanical troubles, if any. Doubtless some can be adapted to American conditions. The Jennings screen is very simple, and is capable of being developed to a higher pitch of mechanical construction, after the experimental stage has been passed.

Specifications.—The writer thinks that, for the purchase of screens, the specifications should be drawn to secure a thoroughly satisfactory mechanism with sufficient stability and generous detail to stand the constant wear and tear, particularly if finances preclude duplicate machinery. The removal expected may or may not be a matter of contract. If it is to be guaranteed, it should certainly be defined more rigorously than in a specification recently brought to the writer's notice, in which a removal "equivalent to that of a settling basin" was required.

Results Obtained.—From a study of screening, under working conditions, on industrial wastes, the writer is inclined to believe that from 20 to 35% removal of suspended matter can be obtained with from 30 to 40-mesh screens, under favorable conditions, on certain industrial wastes. He considers, however, the figure of 30% removal, advanced by Mr. Allen, far too high for ordinary domestic sewage, particularly if from a sewer in a combined system with a long concentration time, fed by a large area in which the population uses much water.

Applications.—The writer does not share the enthusiasm expressed by Mr. Allen in his conclusions. Undoubtedly, the use of fine screens for sewage deserves more serious consideration than heretofore, but the results to be obtained are by no means demonstrated as yet. Careful study and skilled tests are required before the art of screening will

Mr. Pearse.

be placed on as accurate and satisfactory a basis as sedimentation is to-day. Comparative results on the same sewage do not indicate that screening, even with a 30-mesh screen, is the equivalent of thorough sedimentation, nor within 50 per cent.

Mr. Allen is right in calling for more fundamental data on efficiencies and costs, and such data will be required before screening will develop widely in the United States. European data are of little value as a general guide to the results to be obtained in the more dilute sewages common in America.

The writer is of the opinion that the application of screening to industrial wastes is a field which has been overlooked. In many industries wastes of a coarse nature are discharged, which do not readily disintegrate. The application of screening in Packingtown, particularly on paunch manure overflows, and in the stockyards, has demonstrated worth. Possibly in tanneries, wool washing plants, and the like, a use may be found under favorable conditions.

In the paper and pulp industry considerable application has already been made to retain pulp which would float away in wash-water. A screen of the drum type has also been tried at Anaheim, Cal., on the waste of a beet sugar works by C. G. Hyde, M. Am. Soc. C. E., with considerable success.

Acknowledgment.—The writer trusts that Mr. Allen will pardon this frank analysis of the situation, as it is thought that it will clear the atmosphere for the future of screening, and encourage the operators of screens to obtain really valuable data. The writer wishes to acknowledge the courtesy of the Trustees of the Sanitary District of Chicago and the Chief Engineer, Mr. George M. Wisner, for material drawn from a forthcoming report.

Mr. Whittemore.

L. C. WHITTEMORE,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read with great interest Mr. Allen's presentation of available data on a branch of sewage treatment practice, as yet little developed in the United States. Extended comment is made by Langdon Pearse, M. Am. Soc. C. E., particularly on the removal efficiencies and reduction in oxygen demand to be expected, as shown by extensive experiments made under his direction for the Sanitary District of Chicago. The limitations of screening in American practice are discussed at length. The writer, therefore, will discuss chiefly two points, wherein fine-screening is likely to be of value in the treatment of packing-house and stockyards wastes, in spite of its obvious limitations as compared with sedimentation. Both have been noticed by Mr. Allen, and are: (1) the possible reduction in rate of sludge accumulation in settling tanks, and (2) the partial or complete prevention

* Chicago, Ill.

of scum formation. The general character of the packing-house sewage is outlined by Mr. Pearse. Mr. Whittemore.

With regard to the first factor, extended investigations have shown that sludge at the rate of 8 to 10 cu. yd. per million gallons may be expected as a result of plain settling in tanks of the Emscher and Dortmund types, based on uniform flow. If corrected to allow for operation at a variable flow, to follow the discharge from the sewer throughout the day, they should probably be increased by 25% or more. With a 30-mesh rotary screen, operating between the hours of 8 A. M. and 4 P. M., an average removal of 950 lb. of dry material per million gallons was obtained. Extending the run to 11 P. M. reduced the average rate to from 320 to about 500 lb. per million gallons. Reduced to sludge of 90% moisture (tank sludges have usually run somewhat higher than this figure), this is equivalent to from 2.0 to 5.5 cu. yd. per million gallons, approximately. Practically nothing was retained between 11 P. M. and 8 A. M., and some reduction in the average removal for the entire day would be necessary. On the other hand, the highest removal occurs during the hours when the flow in the sewer is greatest, and it is evident that material reduction in the rate of sludge accumulation would result with fine-screening. The saving in sludge storage capacity and area required for drying beds, if the sludge is disposed of in this manner, is obvious. A substantial saving in cost of tanks and drying beds should therefore result. Moreover, the screenings are readily handled after slight draining, whereas the tank sludges are liquid, and require several days for drying with the well-digested Emscher product, and considerably longer for other sludges, under favorable conditions. With further removal of moisture, perhaps by pressing, the screenings could probably be disposed of by incineration, as the calorific value of the dry material exceeds 9 000 B. t. u. per lb.

The second point in favor of screening is the prevention of scum formation. Scum has been continuously present in considerable quantities on the various experimental tanks, except where chemical precipitation was used. The high temperature of the sewage (70 to 90° Fahr.) and the rich organic content stimulate vigorous bacterial action, and this, with the high content of grease and light fibrous matter, promotes the rapid accumulation of scum. Comparative experiments in a Dortmund tank in May and June, 1914, under identical conditions (a 3-hour detention period), except that screened sewage was used during the hours of heavy flow in May and raw sewage in June, showed rates of scum accumulation of 0.5 and 3.1 cu. yd. per million gallons, respectively. Scum did not appear at all until the last few days in May, but was continuously present in June, reappearing very shortly after being removed. The difference is striking, and as the scum is neither liquid enough to flow readily, nor sufficiently

Mr. Whittemore.

solid to be easily handled, its removal would entail considerable difficulty in a large installation. The value of scum prevention is very apparent.

The writer fully realizes that his discussion is perhaps rather limited in its application, as the sewage dealt with is of unusual character, but it is hoped that a possible field of usefulness for fine-screening, as an adjunct to, rather than as a substitute for, sedimentation, in treating wastes of this nature, has been demonstrated.

In conclusion, the writer would suggest that percentage efficiencies of removal be scrutinized with care, and the conditions under which they are determined be critically examined before too much credence is given to unusually high removals. A few scattered determinations may lead to an entirely erroneous opinion when based on analysis of small influent and effluent samples by the usual methods. As illustrative of this, it may be of interest to note that, during a 27-day run with the experimental rotary screen, daily efficiencies ranging from an apparent increase of 7% to a reduction of 53% and averaging 32% were found. The screen was operated for 8 hours each day, and influent and effluent samples made up of portions collected every half hour were analyzed by the Gooch crucible method. The rate of flow was constant, and all conditions were particularly favorable for securing accurate results, yet wide differences are noted, and the apparent increase is of course impossible, as a matter of fact. Based on the method of computing the influent analyses, as mentioned by Mr. Pearse, results ranging between 12 and 23% were secured, which are in all probability far nearer the truth. Although the effluent may be affected by errors of sampling and analysis, as well as the influent to a certain extent, it is possible that, when the coarse particles not adequately represented in the analysis are eliminated, the effluent analyses are on the whole more representative, and this method is more trustworthy where the flow and weight of screenings can be ascertained accurately. In relation to this matter, the writer would express the opinion that calculating the efficiencies of screens to tenths or even hundredths of 1% is entirely unwarranted, when consideration is given to the accuracy of the data on which they must necessarily depend. The nearest percentage is undoubtedly well within the limit of error, and is entirely sufficient for practical purposes, without giving a false idea as to the accuracy of results.

Mr. Greeley.

SAMUEL A. GREELEY,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has been much interested in this comprehensive paper. He inspected the screening plants at Hamburg and Frankfort in June, 1908, and again in September, 1911, at which time he also examined the screening plant at Dresden, then in its first year of operation. It

* Winnetka, Ill.

has been interesting to compare the data secured during these inspections with those given by Mr. Allen. Mr. Greeley.

Hamburg.—The River Elbe divides the city into a larger northern section and a smaller southern section, for each of which there is a screening plant. The older plant described by Mr. Allen is on the river-front, in a very busy, thickly built-up section of the city. Within four blocks are the seaman's school and the entrance to the new tunnel under the river.

The time of flow of sewage to the plant was estimated to be from 2 to 4 hours, depending on the volume. The sewage appeared to be fresh and contained a strikingly large proportion of unbroken fæces.

At the time of the writer's visit in 1911, it was stated that the volume of sewage flowing through the screens was about 50 000 000 gal. per 24 hours. The screens removed from 13 to 65 cu. yd. daily, the average removal being 26 cu. yd. of wet screenings per 24 hours. Mr. Allen states that the removal is 18 cu. yd. per day.

The sludge and screenings are dumped into covered steel barges which are towed to dumping grounds near Neuenfelde, a farming locality along the Elbe, some miles below Hamburg. The tank boats are taken to an unloading station, on a small creek. The station has an inlet for docking the boats, an unloading crane, some small trucks, and a narrow-gauge movable track. The crane lifts the body from the truck to the boat. There it is filled with a shovel, and then replaced on the truck, and run out on the dump. At the time of the writer's visit, the dump was about 5 ft. deep and 75 by 50 ft. in area. It was very foul, giving off a strong pig-pen odor. The material was carted away to the fields in farm wagons.

The country about this unloading station was devoted to truck gardens and orchards, through which the writer walked about 2 miles before coming to the unloading station, and throughout most of this distance the pig-pen odor from the screenings was clearly evident.

Frankfort.—The sewerage of Frankfort is on the combined system. The sewage from the whole city is treated at one disposal plant by screening and sedimentation. As is common in German cities, the sewers are well built and have good slopes, and the sewage comes to the plant in a fairly fresh condition. However, it did not appear to be as fresh as that at Hamburg and Dresden.

The average volume flowing to the treatment plant is about 26 000 000 gal. per 24 hours. The screens remove from 20 to 26 cu. yd. of wet screenings per 24 hours.

The screenings are taken with the sludge from the settling basin to centrifugal drying machines, and the dried material is burned with the city refuse in incinerators. The centrifugal machines are in a large building, and the dried material is handled on conveyors. The

Mr. Greeley.

odors about this part of the plant were very much like those in a garbage reduction building.

It is interesting to note that, up to the latter part of 1909, the sludge and screenings from the Frankfort plant were disposed of on land. This method was unsatisfactory, and the present more costly method of disposal was adopted.

Dresden.—Dresden is sewered on the combined plan. The superintendent at the screening plant informed the writer that the time of flow of sewage from the center of the town to the screening plant was only about 0.5 hour, and for most of the sewage, did not exceed 2.25 hours.

The average quantity of sewage flowing to the plant was 26 500 000 gal. per 24 hours. During storms, this quantity is greatly increased. The superintendent stated that the revolving screens removed from 13 to 16 cu. yd. of wet screenings per 24 hours.

At the time of the writer's visit only one of the disk screens was in operation, and the difference in level of the sewage on the two sides was 11.8 in. The maximum loss of head expected was 23.6 in. The writer was told that the disk screens sometimes required washing with a hose once every hour to remove fat and grease. At other times, one washing on each 8-hour shift was sufficient. One man attended to the ordinary operation of all four screens.

The screenings were taken to long wooden troughs in the yard. These troughs had false bottoms of wood set about 18 in. above the paved floor of the yard. The liquid from the screenings drained to the floor and flowed back in a sewer to the screens. The troughs were roofed over, but not housed in. The dry screenings are said to be good for fertilizing, and are removed by farmers, who pay for the privilege. Although there was only a small accumulation at the plant when seen by the writer, the material was offensive, having the characteristic pig-pen odor.

Percentage of Removal.—It is hard to express the removal of suspended matter by screens as a percentage of the total original suspended matter, because of the difficulty of securing representative samples for analysis. The data on removal, as obtained by the writer, and as given by Mr. Allen, are summarized in Table 24, in which the percentage of removal is shown. This "percentage of removal" is computed from the weight of screenings caught, the percentage of moisture contained in the screenings, and the suspended matter in the crude sewage. The dry material in the screenings, in parts per million, is calculated against the total suspended matter in the crude sewage. Screenings are assumed to weigh 60 lb. per cu. ft.

The percentage of removal at Frankfort, calculated from the content of suspended matter in the crude and screened sewage, is 10 per cent.*

* *Die Frankfurter Kläranlage.*

TABLE 24.—PERCENTAGE OF REMOVAL OF TOTAL SUSPENDED MATTER BY FINE SCREENS. Mr. Greeley.

Plant.	UNDRAINED SCREENINGS, IN CUBIC YARDS PER MILLION GALLONS.		Suspended matter in crude sewage, in parts per million.	Percentage of moisture in screenings.	PERCENTAGE OF REMOVAL:	
	Greeley.	Allen.			Greeley.	Allen.
Hamburg.....	0.52	0.34	300	87	4.4	2.9
Frankfort.....	0.88	2.48	411	85	6.2	17.5
Dresden.....	0.55	0.97	300	84	5.7	10.1

The sewages represented in Table 24 are more concentrated and fresher than is usual in American cities.

Disposal.—Mr. Allen correctly calls attention to the importance of the disposal of screenings when he states that "another and more probable cause for offense lies in the disposal of the screenings". The writer does not consider that Mr. Allen has given sufficient consideration to this difficult problem. The screenings at the plants visited were very unsightly and unpleasant to handle, quickly fouling the cars, conveyors, and chutes, and causing offensive odors. Certainly, when placed on land, the screenings become very foul. Disposal by incineration confined the odors to within the works, but added to the cost of disposal. As the efficiency of screens increases and greater quantities are removed, the disposal problem also increases. When comparing fine-screening with sedimentation, the matter of disposal must be considered.

Summary.—Judging from his investigations, the writer considers that a removal of suspended matter from domestic sewage amounting to 30% is higher than can be expected in ordinary operation and under reasonable limitations of loss of head, cost, present available devices, etc. The available data indicate that a removal of 15% has seldom been reached in practice. The writer's observations lead to the conclusion that the disposal of screenings is attended with the production of odors which may create nuisances, and that adequate methods of disposal of screenings, with reference to cost and efficiency and the location of the place of disposal, are essential parts of an installation of fine screens.

E. KUICHLING,* M. AM. SOC. C. E.—The thanks of all engineers interested in the treatment of sewage are due to the author for his masterly presentation of useful data on the construction and effect of fine screens. It is the first appearance of such comprehensive information in English technical literature, as the subject has received Mr. Kuichling.

* Mr. Kuichling died on November 9th, 1914. This discussion was the last work he did.

Mr. Kuichling.

little attention from English and American engineers until very recently. In Germany, on the other hand, for more than twenty years past, much scientific study has been given to the screening of sewage, with the view of avoiding the great expense of clarification by means of tanks and filters, in places where the effluent could be discharged into relatively large streams without causing appreciable offense; and hence most of the available data found previously were in German publications.

It is claimed that screens with openings from 0.10 to 0.25 in. wide will intercept a large proportion of the floating and suspended solids in sewage, together with the multitude of bacteria adhering thereto and enclosed therein, and that the effluent will consequently be greatly improved in appearance and rendered more easily capable of rapid assimilation by the water of the stream into which it is discharged; also that the removal of such solids will greatly facilitate every other mode of further treatment. Much of this intercepted matter consists of practically non-putrescible substances like paper, cloth, cordage, leather, hair, bone, wood, bark, husks, corks, bread, fat, etc., and the remainder is mostly fresh and dried vegetable matter, such as leaves, stems, parings, rinds, and seeds, together with fragments of meat, fish, membranes, entrails, etc. These latter substances are putrescible, but usually reach the screen in odorless condition. The screenings, therefore, are free from nauseating odors and can be handled inoffensively; they must, however, be removed at frequent intervals and with the least possible comminution, in order to avoid loss of head and defilement of the effluent. To realize these claims, careful design and operation of screens are imperative.

In regard to the quantity of solid matter removed by fine screens, it may be noted that the figures in Table 12 show a range of 0.34 to 5.94 cu. yd. per million gallons, with an average of 1.90 cu. yd., and a range of 0.014 to 0.282 cu. yd. per 1 000 of population daily, with an average of 0.093 cu. yd. Presumably, the reference is to wet material weighing about 1 500 lb. per cu. yd., and containing about 75% of moisture, so that 1 cu. yd. of wet screenings represents about 375 lb. of dry substance. On this basis the aforesaid averages will be 712.5 lb. of dry matter removed per million gallons of sewage, or 85.43 parts by weight per million, and 34.88 lb. per 1 000 persons daily. These quantities are certainly large enough to make a marked improvement in the quality of the sewage, and to reduce materially the volume of troublesome sludge produced by subsequent sedimentation. It can also be inferred that the sludge deposited after the sewage has passed through a fine screen will be much more easily and extensively decomposed by bacterial action than the sludge of unscreened sewage, but comparative experiments in this direction are still lacking.

Mr. Kuichling.

To compare the weight of the dry solids contained in the sedimented sludge of unscreened sewage with that of the screenings, it can be assumed that, on the average, the volume of such sludge is 2 000 gal. per million gallons of sewage; also that the weight of this sludge is 66⅔ lb. per cu. ft., and that it contains 85% of water, so that each cubic foot contains 10 lb. of dry substance. The volume of sludge is thus 267.36 cu. ft. per million gallons of sewage, and hence it contains 2 673.6 lb. of dry matter, while the screenings contain on the average 712.5 lb., or 26.65% of the former. It may be remarked, in this connection, that the plain sedimentation of the sewage of Providence, R. I., during 1912 yielded an average of 1 758 gal. of wet sludge per million gallons, with 9.97% of dry solids; and, if it is assumed that the wet sludge weighs 65 lb. per cu. ft. and contains 6.5 lb. of dry substance, then the said volume of sludge contained 1 527.5 lb. of dry matter per million gallons of sewage. As a fine screen was not used, no further comparison can be made in this case, but, if the aforesaid average of 712.5 lb. of dry matter per million gallons could here be removed by fine screens, the latter would remove 46.65% of that which was removed by plain sedimentation.

The percentage of suspended matter intercepted by a fine screen varies much in different hours of the day, different days of the week, and different months of the year. It is governed to a considerable extent by the nature of the industrial wastes admitted into the sewers, and by the intensity of the rainfall which washes the streets of the city. If there are many shade-trees, and also if the streets are not frequently cleaned, a heavy storm will cause large quantities of leaves, paper, and other débris to enter the sewers in a short period of time, and will also flush out previous deposits in the sewers, thereby greatly increasing the suspended and floating solids. The variation in quantity of matter intercepted by fine screens having meshes or orifices from 0.06 to 0.08 in. in diameter is shown clearly by Metzger's experiments in 1906 and 1910 at Bromberg, Germany.* In the first experiment, with a wire-cloth screen of 0.08 in. mesh, during an entire dry day in 1906, the volume of sewage screened was 1 622 300 U. S. gal., and the weight of the wet material arrested was 8 118.66 lb., thus making an average of 338.28 lb. per hour from an average flow of sewage of 67 596 gal. per hour; and the maximum weight in one hour was 1 334.66 lb., while the minimum weight in one hour was 8.60 lb. In 1910 the second experiment was with a drum screen of thin perforated metal having circular orifices 0.06 in. in diameter; and, during one week, 77 432 lb. of wet screenings were intercepted from 8 402 773 U. S. gal. of sewage, the averages thus being 11 061.7 lb. from 1 200 396 gal. per day; the maximum in one hour was 1 750.45 lb. from 71 064.4 gal. of sewage, and the minimum was so small that the movement

* Described in *Technisches Gemeindeblatt*, Vol. 9 and 13.

Mr. Kuichling.

of the screen could be stopped from 1 to 7 A. M. The wet screenings were deposited in a receptacle and weighed, after decanting the supernatant water, and it was found that the thick pulpy matter left contained 34.3% of moisture. On this basis the aforesaid rates of removal will become an average of 6 054.2 lb. of dry solid matter per million gallons per day, and a maximum of 16 183.1 lb. per million gallons in one hour; and by reducing to parts by weight per million, these figures become, respectively, 724.2 and 1 935.8. The cost of operating this screen for a week was at the rate of $2.45 per million gallons, including all expenses for attendance, oil, waste, air compressor, lighting, and electric power, and it is claimed that this rate will be materially reduced in regular operation.

Data like the foregoing, together with those presented by the author, prove conclusively that fine screens are highly efficient and economical in preparing sewage for admission into comparatively large streams where the dilution of the effluent is permissible; and they also indicate that such devices will prove advantageous in cases where a high degree of purification is required, by relieving settling tanks and filters of a large and undesirable burden. It is to be hoped that comparative experiments will soon be made with the same sewage, which will demonstrate the effect of fine-screening on different modes of sewage treatment.

The chief difficulty in screening sewage is in preventing serious obstruction of the orifices, and in cleaning the apparatus in an unobjectionable manner. Many ingenious devices have been invented to keep the submerged portion of stationary gratings clear, and to remove above water the material intercepted by movable screens. In the former class a considerable quantity of suspended matter is unavoidably comminuted and mixed with the effluent, and in both classes the wet mass must be removed from the moving parts after emerging from the sewage. This removal has hitherto been accomplished by combs, scrapers, brushes, and jets of water, steam, and compressed air; but in all such operations some spattering takes place, whereby finely-divided sewage matter gets into the surrounding air which must be breathed by the attendants, and may thus cause sickness. This danger can be obviated by applying a suction apparatus to the wet screenings and removing them in a pipe to a receptacle, without producing spray and polluting the air. Such a device, however, has not yet been developed, probably because an active demand therefor does not exist.

The speaker became interested in cleaning sewage screens by the suction or vacuum method about 9 years ago, and laid the matter before several makers of vacuum cleaners, as well as a number of skillful mechanical engineers. To his astonishment, these men asserted that wet pulpy material could not be removed from a screen

Mr. Kuichling.

in this way, as the suction pipe would soon become clogged. They did not know that many years ago this process was applied successfully to the cleaning of cesspools and privy vaults, and is still in use in unsewered communities; nor that a distinguished Dutch engineer, Capt. Charles T. Liernur, about 40 years ago, applied it to the removal of excreta through an extensive system of cast-iron pipes laid under the streets of Dordrecht and several other small cities, where the matter was delivered by suction to a central station and there converted by evaporation into a commercial fertilizer. These plants were in operation for many years, and are probably still in use; hence the practicability of the method can be regarded as established.

The designing of fine screens for sewage is essentially a problem for mechanical engineers, but as these devices are used only by civil or municipal engineers, a knowledge of the numerous details involved becomes necessary to the latter. It is not an easy matter to compute the stresses in an inclined disk 30 ft. in diameter, like the Riensch screens at Dresden, subjected to the load of wet screenings and possibly a considerable hydrostatic pressure on a part of its surface; yet the clear recognition of these forces is necessary in order to secure durability and correct action. Means must also be provided for varying automatically the speed of the moving parts, so as to conform to the different hourly quantities of suspended matter intercepted, otherwise there will be either a waste of power or an excessive loss of head by obstruction of the orifices.

Reference may also be made to the loss of head involved in the passage of sewage through a fine screen. The author has cited (page 1889*) a coefficient of discharge of 0.4 for the small slots of a Riensch screen, on the assumption that from one-half to one-third of their area is obstructed. It would be interesting to know how this value was reached, as a much larger figure is commonly used in hydraulic computations. Small orifices and narrow slots in a thin plate of metal have a coefficient of discharge of 0.63 to 0.65, but its value may perhaps become less if the orifice is very irregular in shape. Experiments in this direction are lacking, and few observations of the actual loss of head at a partly clogged screen have been recorded. Estimates of 1 ft. loss of head are occasionally found, whereas at Hamburg the actual loss ranges from 8 to 30 in. It is obvious that this loss might be utilized to control the speed of the moving screen, in order to prevent excessive back-water and the development of internal pressure in a closed conduit.

Of the various fine screens described in the paper, the one invented by Mr. Riensch and manufactured by Mr. Wurl seems to have met with general approval. It has the advantage of presenting a large area to the sewage, thus attaining a minimum loss of head; it is

*Proceedings, Am. Soc. C. E., for August, 1914.

Mr. Kutchling.

also easily cleaned, and when built without a submerged bearing, as indicated by Mr. D'Olier, it can readily be lifted from the sewage for convenient examination or repair; the cleaning is done below the level of the floor used by the attendants, and the revolving brushes can be covered with a hood to prevent the escape of spray and particles of solid matter into the atmosphere; there is no appreciable pressing of soft solids through the slots or orifices by the brushes, and the drippings from the intercepted matter before its removal fall only a short distance into the effluent, thereby reducing the evolution of dissolved gases and odors from the liquid by prolonged exposure and agitation.

All these features must be taken into consideration in designing a fine screen for sewage, both in order to secure efficiency and to render the work of attendance as healthful as possible. At its best, such work is unpleasant, and much more will be accomplished if it is made free from the danger of contracting disease. Economy of construction and operation is the final consideration in a successful design.

WATER SUPPLY OF THE SAN FRANCISCO-OAKLAND METROPOLITAN DISTRICT.

Discussion.*

By Messrs. C. E. Grunsky and William Schuyler Post.

Mr. Grunsky.

C. E. Grunsky,† M. Am. Soc. C. E. (by letter).—In Mr. Cory's presentation of this subject, which is of vital importance to a flourishing and fast growing western section, there is a marked departure from the ordinary treatment by an engineer of an engineering problem. He has endeavored to present a picture of the local circumstances of growth and development of San Francisco Bay communities and of the factors which influence this growth, in order that due weight may be given to social, industrial, agricultural, topographic, and hydrographic conditions when the question of a water supply for the Greater San Francisco of the future is considered. The result is a paper full of interest to the California engineer, but with only few points that may call forth some comment from the engineer who deals with water supplies from the eastern standpoint.

It is plain that the author favors the development of local sources of water supply to the limit, before going far afield for a mountain supply of a higher grade.

The established company, the Spring Valley Water Company, formerly known as the Spring Valley Water-Works, has a developed supply of 35 000 000 gal. per day. This company is at present supplying in excess of this quantity, but at the cost of a gradual depletion of its storage. In California the rain which produces run-off falls within the consecutive 6 months, November to April. There may be from 2 to 3 years in succession with only 50%, or but little more than 50%, of normal rain.

* Continued from November, 1914, *Proceedings*.
† San Francisco, Cal.

Mr. Grunsky.

In the water-sheds from which San Francisco's present supply is obtained, the normal rainfall ranges from about 15 to 50 in. per annum (the latter covering a few square miles only), and, in the years in which the rainfall is but little in excess of the minimum, which may be as low as 40% of the normal, there is hardly any run-off. Due to these conditions, there is need for storage, either on the surface or underground, of practically a 3 years' supply, if the local sources alone are to be made dependable.

Due to this fact, the supply from near-by sources involves, first, large reservoir capacity, and second, in the absence of filtration, the control of vast areas of water-shed, in order that by such ownership adequate sanitary protection can be afforded. The Water Company, in line with these requirements, has constructed reservoirs on the peninsula south of San Francisco, which have an aggregate capacity of about 28 000 000 000 gal., and is now constructing an additional reservoir on the opposite side of the bay, on Calaveras Creek, a tributary of Alameda Creek, which will more than double this capacity. The Water Company, furthermore, in order to protect the quality of the water, and also to safeguard rights to the underground waters of the Livermore Valley, has acquired and holds the fee to more than 100 000 acres of land, much of which, by reason of use as water-shed or as reservoir area, is made non-available for agricultural and residence purposes. The collecting ground is but slightly removed from the bay margin, and is generally of the low rolling hill type. Nearly if not quite one-half of the present San Francisco water supply comes from wells in the Livermore Valley and from the gravels in Sunol Valley. The Sunol gravels are recipients of the summer flow of Calaveras Creek and of lesser feeders of Alameda Creek, and in a small measure afford sub-surface storage. The water is collected from the gravels in a filter gallery.

The wells in the Livermore Valley near Pleasanton were originally Artesian, but the water-table has been drawn down by pumping, so that all water obtained from this source is now pumped.

The combined supply from the Pleasanton wells and from the Sunol gravels, after being carried across the Bay of San Francisco from the Alameda to the peninsula side, is pumped into the Crystal Springs main, so as to arrive in the city at an elevation of about 165 ft. Certain quantities of this water, according to requirement, are pumped to higher levels.

The water intercepted at Pleasanton and at Sunol is that which under natural conditions would have aided in keeping the Niles gravel cone, the delta cone of Alameda Creek, supplied with water. By this interception the natural period of flow of the creek has been reduced, and in some measure the sub-surface waters of a fan-shaped area expanding with distance westward from Niles toward

Mr. Grunsky.

San Francisco Bay have been reduced. This sub-surface supply is drawn upon, as Mr. Cory explains in his paper, by the pumps at Alvarado and elsewhere which supplement the Lake Chabot and other local supplies of Oakland, Alameda, and Berkeley.

It seems probable that the gravels of the Alameda Creek delta cone are being already drawn upon for more water than they can continuously supply. The water-plane near the pumps is lowered below sea level. It remains to be seen how long the draft of the past upon such wells can be maintained without impairing the quality of the water beyond the allowable limit.

The possibility exists, as Mr. Cory points out, of making additions to the developed local supplies, particularly for the cities on the east shore of the bay; but this water development, as in the case of the San Francisco supply, implies the acquisition of large areas of water-shed and of near-by reservoir sites, and, in view of the low, undesirable nature of the collecting ground, ultimate filtration. All this will be at a cost not materially, if at all, less than that of first-class mountain water.

The fact is generally recognized that the population centering around San Francisco Bay cannot depend long on the water from the so-called near-by sources, but must soon go to some remote source for an adequate supply.

The question naturally arises: Which of the remote sources will be the most available? Pumping from the San Joaquin or from the Sacramento River has frequently been advocated, and much is made of the fact that inferior water to that which these streams could provide is made fit for consumption elsewhere by filtration and by treatment with hypochlorite.

Although this may be true, no one who has the choice would advocate the preparation of a filthy water for domestic use when, within the limit of the means at command, a pure mountain water can be made available.

On the basis of an exhaustive analysis, the writer reached the conclusion in 1901 that the cost of developing and delivering a Sierra Nevada supply of water would not be greatly in excess of developing and delivering an equivalent quantity from local sources. The result of his investigations is embodied in a so-called progress report published in the Municipal Records of San Francisco, and his conclusions have been confirmed, particularly in so far as the selection of Tuolumne River as the best source of supply is concerned, by subsequent investigators for the City of San Francisco.

If the city acquires the properties of the Spring Valley Water Company, at the price at which they are to be shortly submitted, it will be at a cost per million gallons of developed water with which the cost of water from the Sierra Nevada, if brought to the bay region

Mr. Grunsky.

in a quantity not less than 60 000 000 gal. per day, would compare favorably.

It would be out of place to attempt a review of the studies which led the writer to make the recommendation that the city make application to the Secretary of the Interior for the right to store waste flood-waters in reservoirs to be constructed at Lake Eleanor and at the Hetch Hetchy Valley, the latter on the main branch of the Tuolumne River; but, though making this definite recommendation and thereupon making the application for the city, through the Mayor, the writer has always been a strong advocate of the acquisition by the city of the established water-works, to which the mountain source of supply would be added.

The writer, as City Engineer of San Francisco from 1900 to 1904, was required to report on a water-works entirely independent of the established system, but, in doing so, he called attention to the proper course to be taken by the city. It is needless to say that he has been disappointed in the result of subsequent proceedings.

The city's application for reservoir sites met with opposition which was directed by Spring Valley Water Company officials. These officials succeeded in alarming the two irrigation districts which were dependent on the Tuolumne River as their source of supply, and thereafter the Water Company, the two irrigation districts, and misguided nature lovers, actively opposed the granting of permits to San Francisco to use the two selected storage sites.

Secretary of the Interior Hitchcock advised that Congressional action in the matter should be sought. His successor, Secretary Garfield, recognized San Francisco's rights, but made the permit which he issued subject to certain conditions, the most onerous of which was the one requiring that the lesser reservoir, Lake Eleanor, be developed first. As the permit was revocable, the next Secretary of the Interior, Mr. Ballinger, unfriendly to the San Francisco project, issued an order to San Francisco to show cause why the permit, in so far as it related to the Hetch Hetchy Valley, should not be revoked.

San Francisco was thus put on the defensive and, due to lack of confidence of various of her official departments in each other, placed this case in the hands of an expert called in from the East. The natural result was that thousands of dollars were needlessly expended in the accumulation of a mass of statistical information, and plans were outlined, not for the San Francisco water supply alone, but for a project to divert from the Tuolumne River more than 600 cu. ft. per sec., and to make use of this water until such time as the cities near the bay required it for irrigation in the bay region.

It was pointed out in the resulting reports that the earlier project, for an initial unit of 60 000 000 gal. per day, was far below the yield of Tuolumne River, and that the city should undertake the larger

project in order to perfect its claim to a larger quantity of water. No assent, of San Francisco or of any of the other cities supposed to be interested in the larger project, has yet been obtained, or has ever been asked for. Mr. Grunsky.

This ambitious project when presented to the Secretary of the Interior led to violent opposition on the part of the owners of land naturally irrigable from the Tuolumne River. These land owners were determined that, if any surplus water in excess of the needs of San Francisco were to be used for irrigation, it should not be used on the other side of the Coast Range.

The representatives of the irrigation interests were therefore in Washington at the hearings, and they neatly accomplished the discomfiture of San Francisco. By claiming that the river would not always afford water enough both for irrigation and the municipal requirements of the Bay Cities, 400 000 000 gal. per day according to the tentative project, the city's experts were put to it to show that the water supply was ample. They did this, at least to their own satisfaction, and then the demand was made by the irrigation districts that, this being so, the permit if granted should be conditioned on the irrigation districts first receiving all the water which they could use beneficially before San Francisco takes any, and that, to the extent necessary to protect the districts in such use, they should be allowed to take San Francisco's stored water at cost.

Instead of refusing to surrender first right to all stored water, the city fell into the trap, as can be seen by reference to the "Raker Law" cited by the author, under which certain rights were granted to San Francisco.

The city's representatives at Washington should have insisted on her prior rights. There should have been no concession of rights in the stored water to the irrigationists. The courage to do this was lacking. At the same time there might well have been, as the writer has always advocated, a cordial co-operation with the irrigation districts, because the city, by storing much more water than called for by its immediate needs, would have been in position for many years in the future, probably for 25, or more, to give annually large volumes of stored water free of cost to the districts, thereby saving to them the need of increasing their fall supply by storage of their own.

San Francisco has apparently now waived her prior rights to the stored flood-water of Tuolumne River. When there is a shortage of supply, it will fall on San Francisco, not on the irrigation districts, which, except for the concession made, as explained, would have had no rights whatever in the water stored by San Francisco, provided, of course, that this storage was made subject to the acknowledged prior rights of the districts to the natural flow of the stream to the limit of these prior rights.

Mr. Grunsky.

San Francisco, under the Raker Law, is to expend from $500 000 to $1 000 000 on the proposed storage works in excess of her own requirements in order to be in a better position to meet the obligation, which she has apparently assumed, to supply some stored water to the irrigation districts.

San Francisco, under the same law, will be required to pay for the appropriated water, which should be hers without cost, under State law, at the rate of $15 000 per year for 10 years beginning in 1919, thereafter $20 000 per year for 10 years, and thereafter $30 000 per year. The present value of these payments exceeds $300 000.

San Francisco must pay excessively for the Government land occupied by its dam sites, by its reservoirs, and by its tunnels, conduits, power-houses, transmission lines, and the like. For these lands, of little or no value (the city already owns the fee of the major portion of the level land in Hetch Hetchy Valley), there must be given in exchange lands of greater value acquired by the city but not necessary in connection with the project.

San Francisco, at the direction of the Secretary of the Interior, must construct roads and trails in the National Forest Reservation in which Lake Eleanor and the Hetch Hetchy Valley are located, at a cost of from $500 000 to $1 000 000, and must provide for the maintenance thereof.

San Francisco is compelled, too, to develop power and to sell a large part of this power at cost in Modesto and Turlock irrigation districts. Perhaps the cost will be determined so as to include a part of the storage, perhaps not, because storage was essential for the other purposes. The sale of power at cost will be of little if any benefit to the San Francisco water-rate payer. The remaining power will be available for use in San Francisco. Its transmission will be over lines about 150 miles in length. It would probably cost less to develop the same power in San Francisco with oil at 75 cents per bbl. than to develop the water power and deliver it over electric wires. Consequently, although of economic value to society, the power feature is likely to prove a burden, and not an advantage, to the project as a whole.

San Francisco has voted bonds for the construction of a 60 000 000-gal. per day project. The bonds voted amount to $45 000 000. These bonds are not available for the new 400 000 000-gal. per day project based on conditional rights to water and on the requirement that a large part thereof be spent in a commercial venture involving the sale of power. The city is proceeding, however, in the development of the power as though its rights in the matter, particularly in reference to the use of this bond money, could not be questioned.

The Hetch Hetchy bonds were voted in November, 1909. They cover a project, as stated, for a supply of 60 000 000 gal. per day

to be obtained from Lake Eleanor under the Garfield permit. They cover also an expenditure possibly of $7 000 000 or $8 000 000 for a distributing system of reservoirs and pipes in San Francisco. They were voted with the understanding, so expressed in the ballot, that, if the purchase of the Spring Valley Water Company's properties in their entirety were sanctioned at the same time by the voters, only $30 000 000 would be available for the works necessary to make the Tuolumne project the auxiliary supply to the established system. The purchase of the Spring Valley system for $35 000 000 at the same election was lost by a few votes short of the necessary two-thirds. Mr. Grunsky.

At the time the city thus voted bonds, there should have been created a Board of Water Supply, free from politics. This was not done. The administration at that time and the administrations that have followed, would not let go. The Mayor, who names the Board of Public Works, and who practically selects the City Engineer for the Board of Public Works, the Supervisors, with the Public Service and Finance Committees, the City Attorney, the Board of Public Works, and the City Engineer, all have a hand in the game.

There is no programme as yet for any change. Within a year there was named a Board of Consulting Engineers to pass upon the hydro-electric features of the first power installation under the unauthorized project, understood to be for 50 000 h.p. These engineers were designated by name in the City Engineer's request for their appointment. From this circumstance alone, it is to be inferred that the political management of the city's water project will be continued. Deplorable as this may seem, it is yet possible that competent management will not be too greatly hampered by political obstruction and political direction; and the hope may be expressed that, despite the unfortunate circumstances of the past, San Francisco may yet achieve an adequate and in every way satisfactory water supply. Nevertheless, the danger should be recognized that competent management of to-day under the political system may be followed by incompetent or even corrupt management to-morrow.

It will be seen from the foregoing that the Hetch Hetchy project under the Raker Law is not the writer's Hetch Hetchy project, and that the new project for water for the entire bay region has not yet been given proper standing by the voters of San Francisco, nor has it yet received the necessary study to determine its main structural features.

Meanwhile the city has made endeavor to buy the established waterworks. According to the latest proposition, to be voted on some time next spring, the Water Company will be allowed to retain several thousand acres of valuable land in and adjoining San Francisco, besides some 5 000 acres of land in Livermore Valley. The value of the Pleasanton wells as a part of the system will be reduced because

Mr. Grunsky.

the maximum draft on them is to be limited to 15 000 000 gal. per day, and because the ownership of the 5 000 acres will carry with it the right to draw on the Livermore gravels for all the water that may be needed on these lands. As these lands are fertile and lie in a region with a mean annual rainfall of only 15 in., the demand for water by them will in time be such that there may not be much water left in the gravels for San Francisco. It seems unfortunate that in the agreement for purchase the limit to 15 000 000 gal. in a single day has been made, because in the future, when San Francisco has a gravity mountain supply, the pumped water from Pleasanton wells will have chief value as an emergency supply and when used in an emergency there should be no restriction on the quantity to be taken in a single day.

The author discusses the local water supplies as though their development, in advance of a good mountain supply of unquestionably superior quality, was a matter of course. If this is his view, there are others who are not convinced that, even on the score of cheapness alone, the development of the local sources first can be justified, and, when quality, quantity, cost, and reliability of service are all taken into account, it is hard to see how any other conclusion can be reached than that the mountain source is the next one which should be developed. There should be 60 000 000 gal. per day added to the supply at present available, and this should be mountain water.

In summarizing the estimate of the total ultimate safe draft for municipal purposes on near-by sources of supply, the author combines the developed and the undeveloped supplies, referring to the aggregate as obtainable at a reasonable cost.

He includes as additional sources all or in part, though perhaps not at the estimates noted in Table 6, which are those of Messrs. Chittenden and Powell.

TABLE 6.

The Peninsula Coast streams, at	50 000 000	gal.	per	day
" Ravenswood and Alviso Wells, at	20 000 000	"	"	"
" Calaveras and San Antonio Branches of Alameda Creek, at	90 000 000	"	"	"
" Area tributary to Livermore Valley, at	40 000 000	"	"	"
Total	200 000 000	"	"	"

Of this quantity (which no doubt includes some over-estimate), only about 15 000 000 gal. per day are actually developed. In the development of the remainder, as already stated, the cost—per million gallons of daily supply—may be as much as, or more than, that of the water from the Tuolumne River, if brought down in a first unit of at least 60 000 000 gal. per day. Some of this remainder will not be obtainable except at the expense of other communities or at a cost

Mr. Grunsky.

to society, which is as necessary to consider as that charged by the author to a Sierra supply.

He includes also from 12 000 000 to 13 000 000 gal. as being furnished by pumping from the Niles gravel cone, and is right in questioning the permanency of a draft of this quantity, and he includes a large development from small creeks in the hills to the east of Oakland, aggregating 21 000 000 gal. per day, and at present developed to but a small extent by the San Leandro Reservoir. When the cost of filtering is considered, and the cost to society, by reason of the occupation of valuable territory, these sources will probably be found to be as expensive as an adequate Sierra supply.

Whether or not this is actually the case, the fact remains that a 60 000 000-gal. first unit from the Tuolumne is within reach, from the standpoint of cost. The development of additional local sources is to be discouraged and not encouraged. The high-grade mountain water should be made available before the possible but improbable development of the nearer sources is awaited.

The writer's conviction remains unshaken that the private concerns on both sides of the Bay of San Francisco should be bought out by the people, and that the entire bay community should then join in perfecting and carrying out as speedily as possible the Tuolumne project, but with suitable modification of the Congressional permit which, unfortunately, is not alone for San Francisco, but also for all Western States, in this, that it establishes a dangerous precedent.

The water supply problems to the northward of San Francisco Bay are separate and distinct from those of San Francisco and the East Bay cities, and need not be brought under discussion in connection with the larger San Francisco problem.

The author presents a diagram, Fig. 15, supposed to represent the latest information relating to rain distribution in central portions of California. This should be used with caution. The precipitation does not increase from north to south in the Sierras, as this diagram indicates, and there is no point known to the writer where, south of the latitude of San Francisco, the precipitation on the western slopes of the Sierra Nevada approaches 80 in. per annum, as shown by the curves of this diagram.

The same suggestion applies to the run-off diagram, Fig. 16. Dependence on the curves there shown, particularly for the Sierra Nevada eastward from San Francisco, might lead to disappointment.

As a contribution to the rainfall and run-off information in the San Francisco Bay region there is submitted herewith the result of a study made by the writer several years ago.

The run-off curves on Plate XLI will show at a glance the limit of the water crop at any point under consideration. Where, as in the

Mr. Grunsky.

case of the Crystal Springs reservoir of the Spring Valley Water Company, the storage capacity is so large that practically no water goes to waste, the run-off shown by the curves, less the loss from the reservoir by evaporation and seepage, will determine its productiveness. The curves afford a quick first approximation of the possible limit of yield.

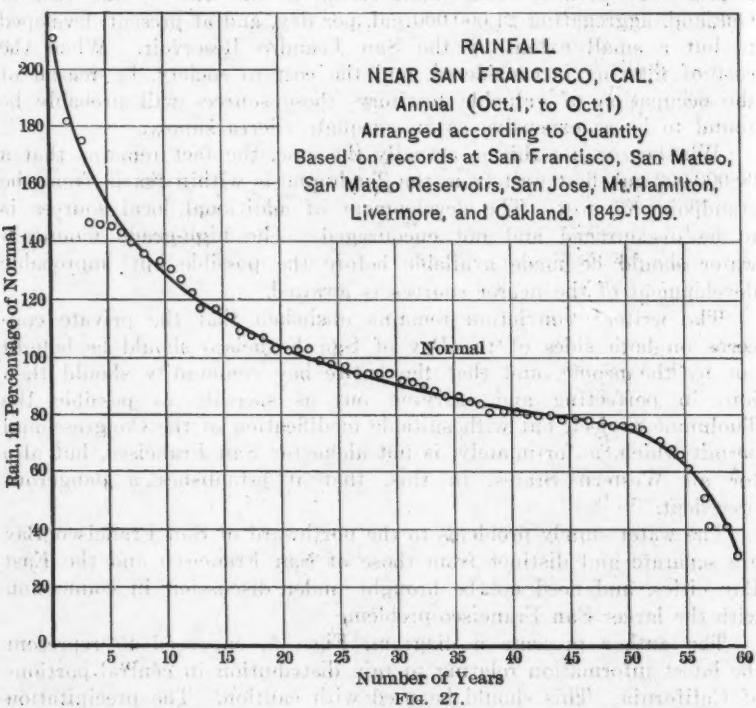

FIG. 27.

The frequency of years of heavy, moderate, and light rainfall in the vicinity of San Francisco are shown by Fig. 27. The rainfall is expressed as a percentage of the normal annual rain in order to give the diagram wider use than just for the locality for which prepared. These data can readily be fitted into a probability diagram to obtain departure from the ordinary law by any one interested in this climatic peculiarity.

Mr. Post.

WILLIAM SCHUYLER POST,* ASSOC. M. AM. SOC. C. E. (by letter).—This paper is an inspiration. It indicates to the engineer a legitimate field which he has abandoned and left to the cultivation of promoters and chambers of commerce. All have smiled at the vagaries

* San Diego, Cal.

of the western "booster", and admitted that people were fools to believe; but we have "stood for it", and have not realized that here is a real science of economic importance, one which the engineer is competent to pass on, and which he should pass on—the assigning of values to elements of civic growth, assigning weights to these values, and making a logical deduction from the known to the predicted. Mr. Post.

It is an ordinary platitude that a city must look 50 years ahead in its water supply. The simple matter of width of streets is left to the accident of original dedication. The cost of future congested traffic and the economic wastes of inadequate or over-adequate present construction and planning all belong to a group which invites the intellectual and imaginative qualifications of the engineer, wherein, working in the present, he foresees, provides for, and harmonizes, the economic situation a decade or more beyond.

As an Angeleno, and with a more or less profound geologic knowledge, the writer cannot admit that the San Francisco fault line runs near Los Angeles. In fact, he believes that the nearest active fault is 60 miles distant, and earthquake disturbance is in reality negligible in Los Angeles. However, the writer enjoys admitting that the eastern colonist puts all California in the earthquake class, and balances it in his mind with cyclones in the Middle West. Therefore, as far as the psychology of the colonist is concerned, before he starts for the coast, the conclusion of Reason 12 is sound; and therein lies the interest of such investigations as these.

AMERICAN SOCIETY OF CIVIL ENGINEERS

THE VALUATION OF PUBLIC UTILITY PROPERTY.

Discussion.*

By MESSRS. ALEX DOW and F. LAVIS.

ALEX DOW,† M. AM. SOC. C. E. (by letter).—Mr. Gandolfo, after noting the existence of a lack of unanimity among engineers, financiers, and the judiciary, asks: Mr. Dow.

"For example, in making a valuation, should actual cost to date, cost of reproduction new, or fair or market value, be used?"

Why the question? A valuation is a valuation, and a statement of cost is a statement of cost. The two are not the same, and there should be no confusion between them in the mind of an engineer. A statement of what a property has cost can be prepared by a competent accountant from the books of the company, unless the books have been wilfully falsified. A valuation is an engineer's work, and the manner of making it is properly a subject of discussion by this Society. The problem is: Given a certain property, required a valuation. The answer is: An itemized list of the property on an assigned date, and the value thereof, as of the same date, as found by the competent engineer.

It may be that the engineer's instructions are that he shall determine the cost of a certain property, to its present or past owners. In that case, no engineering knowledge of values is required, or of use, except as a check on the accuracy of the cost figures shown by the record; and an engineer accepting such instructions presumably either has himself the necessary knowledge of accounts, or will secure competent assistance for the fulfillment of the instructions accepted. In-

* This discussion (of the paper by J. H. Gandolfo, Assoc. M. Am. Soc. C. E., published in October, 1914, *Proceedings*, and presented at the Meeting of November 18th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

† Detroit, Mich.

Mr. Dow. structions to make a valuation or appraisal, however, do not require, except collaterally, the ascertainment of cost, and instructions to ascertain cost do not call for valuation or knowledge of values. Why the confusion between the two which seems to exist in the author's mind and in those of many other engineers?

On page 2452,* Mr. Gandolfo says:

"In any valuation for the purpose of rate-making, or for regulating the issuance of securities, actual cost to date is the final figure that should be used."

How is the purpose of a valuation related to the ascertainment of value? Or is it related at all? In such talk, as to the purpose of valuation, are we not departing from the engineering standard which requires an engineer to tell the truth as he finds it, without fear or favor? Are we not setting up a false standard permitting that an engineer's opinion of value shall be different when his client proposes to buy, from what it is when he proposes to sell? Is it not the duty of an engineer called on to make a valuation to say that he finds certain property the present value of which is thus and so? If the engineer's opinion is asked as to what would be a wise price to be accepted or offered for that property; or if he is appointed arbitrator to fix a price; or if he is asked to express an opinion as to a fair rate of return to be allowed on the property in a rate-making case—under any of these conditions, an opinion as to price or as to rate of return is proper; but, to inject his opinion as to price or as to rate of return into his findings of value is to depart from his direct function as an engineer telling what he has found and at what he appraises its present value for its use or purpose; and, to confuse opinion as to price, or as to rate of return, with value of property as it exists, is darkening of counsel.

In the writer's opinion three-fourths of the existing confusion tending to discredit engineering reports of public utility values arises from the failure (or the refusal) to recognize existing value and recorded cost as two distinct things; the other fourth arises from permitting the interest or intention of the client to influence the report of the engineer as to findings of fact. The way out of the confusion is: First, to recognize the fact that value is value and cost is cost, and that the setting of a rate of return or a permissible price is a function outside of, and beyond the making of, a valuation, or the ascertainment of cost; and, second, to recognize and observe fully the distinction between an engineer's appraisal of value as found, and the opinion or argument of a retained expert.

Mr. Lavis. F. LAVIS,† M. AM. SOC. C. E.—The avowed purpose of this paper is to demonstrate that "the proper figure to be used [for the valuation of public utility property] is the actual cost to date", questions of

* *Proceedings*, Am. Soc. C. E., October, 1914.
† New York City.

fraud, extravagance, mismanagement, etc., being supposed to be eliminated. Mr. Lavis.

The speaker does not agree with this, and, considering the very able paper by Mr. Alvord,* it hardly seems necessary to go into any very extended argument to attempt to show that the "actual cost to date" method is impractical, and that the "cost of reproduction" method appears to be the only one which most nearly complies with all the necessities of the situation.

Mr. Alvord points out the necessity of keeping clearly in mind the distinction between cost and value, and it seems to the speaker that as far as any part of the discussion may be applied to the valuation of steam-operated railways, and particularly to those engaged in interstate commerce, it would appear at once that a valuation based on the actual cost to date method, even though it were possible to apply it, would by no means necessarily give a true estimate of the "present-day value."

One must also not lose sight of the fact that, according to most of the Court decisions, and for the purposes of most valuations, the present-day value is further limited and defined by the requirement that this shall be "the value of the property for the purpose for which it is being used", and it is keeping this in mind which makes it sometimes difficult to see why depreciation should be deducted from the reproduction cost of a machine which is working at 100% efficiency.

Of course, we need not lose sight of the fact that much assistance can be derived from knowledge of actual costs in determining present-day values, or the fact that it is the duty of those charged with the determination of present-day values to use such information for all it is worth. Every railroad engineer of experience, however, knows the difficulty, not to say in many cases the absolute impossibility, owing to the lack of records, of determining for many—even for most—of the important railway systems what the actual cost to date is or what the actual cost of even a reasonable percentage of its component parts has been.

Take, for instance, the very simple and common case of a road which had originally been built as a single-track line and afterward widened, without introducing any questions of changes of gradient or location, though these have almost always been present to add an additional complication. Widening a cut of a line already in operation may cost more for the excavation than it would to have taken it out altogether in the first place, by reason of interruptions of traffic and other difficulties, or it might cost less, by reason of the fact that the presence of the existing line afforded better and easier facilities for doing the work. The value of such a cutting to-day, however, is not

* *Proceedings*, Am. Soc. C. E., for October, 1914.

Mr. Lavis.

changed in any way by the fact that it was all taken out 20 years ago, or part of it 20 years ago and part of it 10 years ago, though these facts most probably did affect its cost.

It is quite true that individual cases might be cited to show that in instances similar to that just referred to the actual cost to date method might be a true measure of the present-day cost, but that hardly alters the fact that, in general, it probably is not, or at least not necessarily so. Arguments can be advanced and concrete instances quoted to show the injustice, under certain conditions, of any method of valuation as applied to individual cases, but, admitting that valuations of railways have to be made, and especially looking at the matter from the standpoint of the Interstate Commerce Commission, some general method must be adopted which will be equally applicable and fair to all the railways of the country, to determine with a reasonable degree of accuracy and fairness their present-day value, which may or may not be the actual cost to date, and most likely would not be.

So many arguments and concrete cases bearing on this phase of the subject have already been published in the *Transactions* of the Society, that it seems only necessary to refer briefly to the matter in this discussion in order that Mr. Gandolfo's statements may not become part of its official records without some protest.

FUNDAMENTAL PRINCIPLES OF PUBLIC UTILITY VALUATION.

Discussion.*

By Messrs. Lewis M. Haupt, L. L. Jewel, Richard T. Dana, F. Lavis, Louis L. Tribus, Joseph Mayer, and Philip Burgess.

Mr. Haupt.

Lewis M. Haupt,† M. Am. Soc. C. E. (by letter).—This paper is an able and timely exposition of a vital question affecting the public weal and concerning which the Engineering Profession has much to do.

The author has stated the fundamental elements clearly, as being legal, economic, and constructive, and has given the definitions necessary to reach clear and just conceptions of their relations to one another as well as the constitutional basis of an equitable settlement for private property taken for public use, under the right of eminent domain.

Yet it seems there are other factors not so readily ascertained, which enter into the solution of the just value. These factors are psychological and are influenced largely by the relations of those who take part in such adjudication. These the author has classified under six heads, the first three of which he rejects as useless and the next two as of doubtful expediency, depending on the trend of their bias. The sixth is the only condition under which one would be apt to render an impartial judgment, that is, the "unbiased and analytical mind that has had ample experience in representing both sides of the question."

In other words, the judge must be competent to determine present values of property as well as franchises, and be a follower of the Golden Rule. Thus, there is introduced the fourth fundamental ele-

* This discussion (of the paper by John W. Alvord, M. Am. Soc. C. E., published in October, 1914, *Proceedings*, and presented at the meeting of November 18th, 1914), is printed in *Proceedings* in order that the views expressed may be brought before all members for further discussion.

† Philadelphia, Pa.

Mr. Haupt. ment of morality as over against policy, which is so often a dominant factor.

In practice how often does it happen that the evidence is tainted with the desire to win the case at all hazards, or that the witnesses—employees—are suborned by the fear of losing their positions if the truth be told, on the theory that "whose bread I eat, his song I sing"; or the impression that to depreciate value and force the holders of private property to sell at a bargain-counter price is a popular measure and will be sanctioned by the public at large, or that the Government consists of those executives who may be temporarily in power and who are paid to drive hard-and-fast bargains with the people, even to the destruction and confiscation of personal or corporate property, at public expense, which the Fifth Amendment was expressly designed to prevent.

One has only to examine the records of the acquisition of the private waterways and other utilities of the country, or on the Isthmus, to note that the first effect of such a measure is to depress the market values of the securities of prosperous "going concerns", and that in some instances official appraisements are made on depreciated unit prices or reduced quantities of materials, and claims are made for services, or threats that free, competitive, parallel routes will be constructed out of the public treasury, at much greater cost, unless the parties who have invested their funds in good faith and are dependent on returns of interest for their subsistence, consent to surrender for less than half the appraised value, as has recently been attempted.

Surely such methods cannot receive the sanction of honorable engineers much less of a righteous nation, yet they have been proposed but have failed in some instances.

In a democracy, such as this, it would seem that what is just for the whole people as sovereign should be equally just for each individual unit, and that if a statute runs against the individual or the corporation, it should also hold against all the people, who are "the Government." The monarchical fiction holds that "the King can do no wrong" and, therefore, excepts the sovereign from the penalties which it compels the individual (who is far less able) to pay, and he has no redress at Court, and relief by legislation is a vain hope.

A Definite Method.—As to the difficulties of ascertaining the present worth of a public utility, it may be apropos to call attention to the acquisition of the property of the Monongahela Navigation Company which, for many years, was a private enterprise furnishing a means for providing the great manufacturing districts in and around Pittsburgh with coal, at very low figures, until it was thought best to emancipate the tolls by having the Government acquire the property and operate it at the expense of all the people. The argument

Mr. Haupt.

presented was that the Government had developed an open waterway on the Kanawha in competition with the Pittsburgh District which was subject to tolls and paid a tax to the State for its franchise.

The Company was inaugurated under a Pennsylvania State charter on June 14th, 1836, and developed "an immense commerce." The Act provided that the works might be purchased after 25 years by paying the expense of construction and repairs, with the net dividends, with 8% interest thereon. The work was actually completed in 1884. The Government Board found (in 1895) that "the money value of the commerce is very great and far in excess of that of a majority of streams upon which the United States, under its policy of fostering commerce, has expended millions of dollars in improvements."

The President of the Company states that "previous to the recent agitation of the question of purchase by the United States the stock sold at a premium of 80 per cent. * * *, making the present value of the Company's improvement, on a basis of 4½% interest, over $4 000 000." Concerning which the Board states that the number of shares and their market value being variable, it was unable to fix on any amount which properly represents such value at any future time.

The books of the Company show the cost of construction and repairs to have been $3 033 531.34. The Board found "the present intrinsic value of existing works about $1 950 000", exclusive of the franchise.

On October 12th, 1886, President Moorhead stated to the Board, "we wish to be left in the undisturbed possession of our property, and protest that no public interest can be subserved by its appropriation by the United States; that the cost of coal to the consumer will hardly be appreciably diminished, while the annual charges to the United States would be burdensome and increasing, as permanent repairs would be required * * *. It would constitute class legislation of the most objectionable kind. The rates of tolls are the lowest charged on any canal or slack-water improvement in the United States and so low that to take them off altogether would not lessen the price of coal 1 cent per ton * * *. The Government cannot take this property without making compensation, which is the full value of the property of the Company."

No dividends were declared between 1839 and 1853, during which time the construction was in progress.*

These negotiations were continued from 1884 to 1907, when the final award was made, by a jury, for the sum of $3 761 615.46, after 23 years of delay. At this date the value of the works and franchises had increased, as shown by Fig. 1, to about $6 335 000, if capitalized

* Ex. Doc. No. 249, H. R. 53d Cong., 3d Sess., Jan. 1895.

Mr. Haupt.

at 4% on the average annual increment of $5 000 net. By this method the actual financial status of the utility is clearly set forth, as it shows the gross receipts from the capital invested, the cost of construction, maintenance, and operation; the influence of social, physical, and commercial agencies during the life of the enterprise and the average net returns, so that, under the doctrine of probabilities, the curve of future value at any given date may be closely approximated.

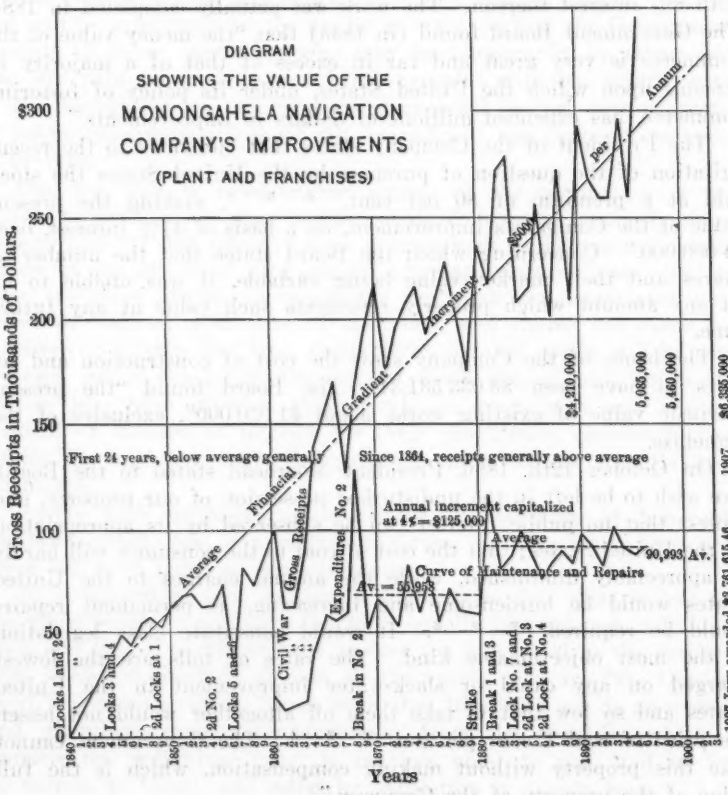

FIG. 1.

It eliminates, also, to a very great extent, the personal equation or erroneous judgment due to the desires of the parties at interest, either of buyer or seller, as it deals only with the facts as measured in dollars and cents and, therefore, should commend itself to all parties who may be retained to ascertain the "just compensation" which should always be paid when a private utility is to be acquired for public convenience.

Mr. Haupt.

In another instance, the Government has been negotiating for an important strategic canal route, of great utility, for more than 40 years concerning which the Chief of Engineers has reported that it would save $1 229 242 on the actual commerce now using it, and "probably considerably in excess of this amount", so that, to effect such an economy (regardless of risks and insurance), it would be justifiable to expend more than $30 000 000, if capitalized at 4%, and yet it hesitates to invest even one-third of this sum for the development of our domestic commerce. Surely an enterprise of such great utility should commend itself for immediate development.

Mr. Jewel.

L. L. JEWEL,* M. AM. SOC. C. E. (by letter).—This paper has been read with a great deal of interest and admiration. It is a masterly presentation of a difficult and complicated subject, and could have been made only after a close and unbiased study of the relations between private interests on the one hand and community interests on the other.

In studying the lines of evidence of value which are summarized on page 2413,† one is impressed with the unimportance, or rather, say, the indirect character, of some of them. For example, the market value of the securities of a property will very rarely, and may never, have any direct relation to its value. Even when there is a broad, free market for them, and the state of mind and of finances of the investing public is normal and undisturbed by any of the thousands of factors that may and do disturb it, the market value of the securities of a property will, to quote the author's apt phrase, reflect more "the hopes or fears for the morrow" than the value of to-day.

Again, the values of other properties similarly situated will seldom be available, and, when they are, could hardly be used except for purposes of comparison with a value already fixed by direct evidence.

Finally, it is hard to see how past cost necessarily has any relation whatever to present value. It is a measure of the efficiency—perhaps the honesty—of promotion, of construction, and of operation; but it certainly can be no dependable measure of present value, nor necessarily have any determinable relation to it.

It would seem, therefore, that the lines of evidence of value as given may be separated into two groups or classes: one containing the lines of direct evidence of value, and the other the lines of evidence which are always of secondary and often of no importance in determining value, but which, nevertheless, may be to some extent useful as a check or balance on the result obtained from direct sources. That is to say, the just value of a property for any purpose in which the consuming public is interested is directly dependent on two factors:

* Wytheville, Va.

† *Proceedings*, Am. Soc. C. E., for October, 1914.

Mr. Jewel. (1) The cost of reproduction, starting with a naked idea and finishing with a going concern, as it is;

(2) What may be called a business estimate of value, depending on the many factors and conditions peculiar to that particular property and community as given by the author in the paragraph called "Fourth" on page 2413.*

A value thus determined could hardly be influenced, although it might be checked, by the other lines of evidence given.

Such a classification of the author's lines of evidence may be criticized as encroaching on the judicial function of weighing the evidence, and as being outside the scope of the paper. It seems to the writer, however, to be not only in harmony with the ideas expressed throughout the paper and with the foundation laid down by the law, but also to be of universal application, and therefore a fundamental principle of public utility valuation.

Mr. Dana. RICHARD T. DANA,† M. AM. SOC. C. E. (by letter).—The author, as he says himself, has assumed an ambitious task, and has produced a work that, if only for the emphasis so skilfully laid on the necessity for dependence on legal principles, cannot fail to further materially the development of scientific methods of appraisal work. The bibliography of legal decisions is timely and valuable. Perhaps People *ex rel.* Kings County Lighting Company *vs.* Wilcox *et al.*, and the Spokane Rate case, might profitably be added. The final paragraph of the paper, defining what the author calls a Golden Rule for the engineering appraiser in valuation work, is more than admirable.

Some of the definitions on pages 2392, 2393* are hardly as comprehensive as would seem to be necessary, in view of the fact that they are intended to establish a definitive basis for the development of principles heretofore somewhat obscure. Two, in particular, will be mentioned: "Property" and "Value". "That which belongs exclusively to an individual" is, in the writer's judgment, a rather inadequate description of "Property". Property connotes proprietorship, and proprietorship may be exercised by a corporation, a firm, a Government, or State, etc., each of which is distinctive, and may not be an individual. "The right of possession" seems to be hardly in the same generic class as the thing possessed, and is objectionable to the writer on that account. Webster's Dictionary recognizes both meanings of the term, but takes pains to separate them.

Economists have striven to define the term "value" satisfactorily, with but poor success to date. "A measure of the relation of two services growing out of the adjustment of mutual needs" implies, to the writer's mind, a good deal of abstruse theory. In its fundamental

* *Proceedings*, Am. Soc. C. E., for October, 1914.

† New York City.

concept, and postulating labor as the basic principle of wealth, this definition may be theoretically correct, but, for practical purposes in appraisal work, it seems to be too complicated. The other definition of this term, given by the author, seems to be hardly adequate, as the undesirable qualities certainly affect the value, and should be considered. Mr. Dana.

Any definition of value which presupposes a free market, a willing purchaser, a perfect and inflexible medium of exchange, is necessarily too restrictive. The science of economics needs for this term a better definition than any which has appeared thus far. Value is not cost, it is not price. For appraisal purposes, the value of a property might perhaps be called the quantity of its net assets, physical and non-physical, all expressed on the same basis of currency.

On page 2396* Mr. Alvord deprecates a "Jack of all Trades", particularly in appraisals, but he does not make it exactly clear, at least to the writer, just who ought to do most of the appraising, the "experts from several professions", or "engineering specialists from each type of utilities to be valued".

In every public utility corporation of considerable size there are usually several very able engineers who are thoroughly familiar with the property because of long connection with it and intimate association with its problems. These men, under the general direction of an engineer who has specialized in economics, costs, and appraisals, will make the best possible "team" for the solution of the composite problems that are inseparable from any appraisal, as has been proved many a time and oft. It has also been proved, to the tune of many millions of dollars, that the appraisal specialist need not be a specialist in electricity in order to make the best appraisal of an electric plant. Some of the worst appraisers of railroad property have been railroad men, some of the best painters have been poor judges of the value of pictures painted by others. To appraise an egg properly, one need not have been a hen.

Moreover, a specialist in economics, and of general engineering training, can find values in one kind of property to which he is led by knowledge of analogous values in another kind of property, which would be overlooked without such general experience.

Granted equal age and intelligence, the man who has had experience of appraising utilities of many kinds will make a better appraisal of any one kind than will he who has confined himself to that one kind of utility all his life, without opportunity to adapt the ideas gleaned from a wider field. This principle, indeed, is fundamental in all managerial processes, of which appraising is not the least.

* *Proceedings*, Am. Soc. C. E., for October, 1914.

Mr. Lavis.

F. LAVIS,* M. AM. SOC. C. E.—The Society and the Engineering Profession are to be congratulated on this valuable addition to the now somewhat voluminous literature on the subject of valuation. This discussion of the fundamental principles, and the clear definition of the points which can be defined, as well as the discussion of those about which there is still some doubt, will do a great deal toward placing the subject on a somewhat more rational basis than that on which it has hitherto seemed to rest.

The whole paper will well repay careful study, but there are some points which the speaker believes may be especially emphasized:

First.—That, although the reproduction method seems to be most generally applicable, there can be no absolutely hard-and-fast rules laid down to govern the methods to be used. It seems most important to point out that each case must be considered on its merits.

Second.—The necessity of collecting and properly arranging all the facts and data relating to each individual case before attempting to formulate opinions.

Third.—The six items cited as necessary to remember, in weighing evidence as to value, especially the first, referring to the fact that value can never be absolute, but is always a matter of intelligent opinion.

Fourth.—The very vivid description (on page 2416†) of the development process. Most particularly apropos being the reference to the "easy and virtuous hindsight" that tells us how the property might be reproduced by supermen, instead of causing us to remember some of our own very human lack of foresight which, to some extent at least, has increased, in some way, the cost of every piece of construction with which we have been connected.

Fifth.—The imperative necessity that engineers must be guided by the law as it exists and as it has been interpreted by the Courts. This, however, though eminently desirable, need not cause us to forget that both the law and its interpretation are subject to changes, and are sometimes at least viewed "in the light of reason" which we might possibly be able to make shine.

In the enumeration (on page 2413*) of those items which must be considered in order to arrive at the cost of reproduction, Mr. Alvord is very careful to point out specifically, in Item *D*, the necessity of estimating the depreciation, but he does not call attention to the equally important necessity of including also the appreciation. It is true, of course, that an intelligent estimate of the cost of reproduction in itself would cover the estimation of both appreciation and depreciation, and, therefore, both may be considered to be covered by Item

* New York City.

† *Proceedings*, Am. Soc. C. E., for October, 1914.

C; but as long as Item *D* was thought to be a necessary supplement to Item *C*, it would appear to be desirable also to include a further note in regard to appreciation, especially as this is so much more likely not to be fully allowed. Mr. Lavis.

There is probably a question as to how far engineers may go toward the determination of the complete value of any live operated property, especially of transportation systems. Mr. Alvord very appropriately points out the necessary co-operation of those experienced in the law, and in economics or finance, as well as engineering, in arriving at this final result. As far as the railways are concerned, it is equally necessary to obtain the aid of those skilled in operation, in traffic and its sources and destinations, and in other allied features, as they usually have a far more adequate idea than engineers as to the costs of development—a most important item of value.

The speaker is almost entirely in accord with the views expressed in the paper, and believes that, speaking generally, they apply equally well to all valuation. The paper, however, is distinctly written from the viewpoint of their particular application to the circumscribed and unified types of utilities, such as lighting and water supply, or even electric railway plants, rather than to steam railways, and this must be kept in mind. This is particularly noticeable in the statement that it is a "demonstrated fact that earnings from public utility investments do not fluctuate so greatly in financial depressions as do some other forms of investment." This most assuredly does not apply to steam railroads, but is generally true of utilities supplying individual municipal needs.

As far as these two general types of properties are concerned, there might be little difference in the principles governing their valuation were it not for the question of the use which it is proposed to make of such valuation when it is made. Valuations are made for many purposes, but the one which is of the most vital present interest is the use of this value for the purpose of the regulation of rates. It is when considering the values of properties for this purpose that the railway situation exhibits difficulties which do not seem to present themselves when considering isolated and complete units.

It is hardly necessary to quote individual cases or examples, as these will readily occur to those having experience in the railroad situation; it does seem worth while, however, to call attention to this point, and to the natural corollary, that therefore neither the market value of securities nor the past or present earnings can be used in the determination of values for this purpose.

Louis L. Tribus,* M. Am. Soc. C. E.—Many of the current articles on utility valuation give evidence of idiosyncrasies, but Mr. Alvord's paper should be considered as a very able, interesting, and comprehen- Mr. Tribus

* New York City.

Mr. Tribus.

sive presentation of rules and methods of arriving at values, together with much basic information and many common-sense comments.

In the speaker's earlier days, the then older engineers, trained largely in the "School of Hard Knocks", were looked up to admiringly, for from them emanated an atmosphere of good sense, and in their infrequent writings and discussions were found the epitomes of judgment, founded on sound principles, because they were the result of well-digested practical successes and failures.

Ofttimes, these same men could not, or would not, formulate the theories on which their works were built or deduce conclusions from them.

Engineers were but little bound by precedent, so that individual thought had fairly free rein.

This is not telling of the remote past, but facts prevailing within very recent years.

About 15 years ago, virtually began the great consolidation of allied interests and an awakening to the possibility of increased efficiency in management; valuation work as now known was then born, though only a crystallized phase of a principle prevailing from the days of Cain and Abel. Unfortunately, with the extreme swing of the pendulum, "efficiency" has become a word more nearly for ridicule than admiration, because many, even excellent, engineers have been led astray by the allurements of blank forms and colored inks, substituting a phantom for reality, and valuation as a newer hobby may easily reach the same goal.

Socialism is now the ruling doctrine of America, even if we do not fully acknowledge it, and unless level-headed men will interject common sense into public thought, there is no knowing to what extremes it may lead. The present public attitude toward public utilities is a marked example.

Engineers have been receiving an increasingly thorough technical training, though perhaps too much specialized at the start, and writers like Mr. Alvord have, sometimes with great clearness, made available for even the tyro, thorough discussions of subjects not found in textbooks and almost unknown to the teacher of a few years past. The teacher's good sense, however, often put into the mind of the student the broad principles which enabled him to make good selections of mental tools and meet the successive problems of practice with credit.

The socialistic idea, however, has already secured dominance in our larger cities, in the legislatures, and even in the Courts, with some phases to the advantage of the public, but not all.

This is nowhere more prominent than in the treatment of the public service corporations. Where is the group of capitalists willing to-day to invest in a new to-be-privately-owned water-works system? There is no safety in such ownership, with the restricted franchise,

Mr Tribus.

the low-rate, short-term hydrant contracts, subjected to the whims of constantly changing city officials, virtual confiscation of property at the end of the franchise period, and constant supervision and regulation of rates by public service commissions. Engineers are not wholly free from blame in producing that effect.

In the speaker's hearing, a well-known engineer objected to a certain city paying to a small water company any material sum for its plant, because "the city could not use it as a part of the larger system, which it would construct at some indefinite time, when it got ready." The company had not had a successful financial career, but had made possible the growth and development of the community served, bringing to the city, in increased taxes, far more than the interest on any sum that might have been required to purchase the plant. In many a valuation case the parties representing those in power have indicated a similar sentiment, though rarely so shortly or brutally expressed.

The horse trade referred to in the paper is the typical basis of all valuations for sale or acquisition of a public utility, except that, when a community is the purchaser, it wields an absolutely unfair advantage, for it can enter into ruinous competition and collect in the tax levy all losses, while the private owner goes steadily into bankruptcy, or accepts the offer made, whatever loss may be entailed.

Granted that arbitration of some form is resorted to, the owners are placed in the position of a defendant who has to prove every item of value rather than have his claims disproved by the community, consequently often many items of real value and legitimate expense are lost in the summations.

How are proper figures to be reached? Here comes the value of such theories as described by this paper and others somewhat similar.

Applying several of the methods will give several differing resultants; now for the horse trader's reasoning: The horse may live for so many years, he may encounter no accidents or illness, therefore he will be able to make good return on the purchase price; the would-be purchaser fixes $200 as the reasonable value, but might pay more, yet cannily offers $175. The seller thinks along the same lines, but remembers some veterinarian's bills, a large feed account, and some lost time, yet also has in mind some excellent earnings; he thinks of $275 with longing, but $225 rather than run risks, and asks $250. Finally, $225 is reached by dickering. No rule of Court based on comprehensive valuing would have brought that result, and thus is it with more important work. The expert evidence worked out on various bases produces an effect on the mind of the jury or Court, but judgment—or sometimes averages—determines the final decision.

If the arbitrators wish to convey the impression of great learning and very careful weighing of the evidence, a "dictum" accompanies the "opinion", and a "rule of Court" is born, to be quoted for all

Mr. Tribus.

time as a guide in other cases, to be followed, perchance, as sheep follow a leader.

Socialistic sentiment is at heart founded on absolute justice between man and man, but socialistic action and legislation is more the result of the one-time-oppressed squaring accounts (and a little more) with the oppressor.

The public utility operator of the past, as a class, has not served the public with strict justice and consideration, and so is not entirely free from responsibility for the judgment often meted out to-day.

All the more reason why the engineer called into a valuation case shall be fair in his advice, as well as intelligent and comprehensive in his study.

That brings us to the point that is too often overlooked, no two cases, generally speaking, are alike or will bear the imposition of the same rules.

It is incumbent, therefore, for the engineer to make a study of the local conditions that affect the utility, its origin and financing, its construction, its operations, its effect on the community, its financial rewards or, perchance, losses, its obsolescence, whether due to poor original judgment, or to radical improvements in machinery, methods, etc., in fact, all the many factors which enter into success or failure.

Then, applying such methods as seem to have applicability, figures will be derived that can have some force in determining the final "horse-trade" judgment.

Without following certain illustrious examples, in condemning the Courts, quietly, engineers may remember that at one time many decisions happened to favor those in litigation who were represented by particular lawyers retained by the party having the longest purse, but to-day votes are more apt to prevail, the decision going to interests wielding the balance of power.

Sometimes non-residence ownership enters the problem, not that the engineer should consider it a factor, but to look out for it and forestall injustice by the thoroughness of his presentation of facts and deductions.

In this discussion the engineer is considered as a judge, not as an advocate; of course he may advise counsel as to points favorable to his side, but on the stand he must be absolutely impartial; and a righteous judge will give great weight to the testimony of a just engineer. We would not intimate, either, that the unrighteous judge is in the majority; something in the nature of such a trust brings out the fair qualities of a man, if they are in him, but too often, influence is stronger than right.

Valuations for rate-making, and taxation, are simply different phases of the same problem, only giving to a possibly injured owner a little greater chance for later redress through review.

Mr. Tribus.

The one point that the speaker wishes to emphasize strongly is the futility of rules for reaching decision as to value, though their benefit is unquestioned for suggesting a range of values, which may be somewhere near the truth; more important than all, however, is a thorough study of all the different factors in light of prior experience as to the financing, designing, constructing, and operating problems involved in the utility under discussion.

The engineer without practical experience is as valueless in handling such questions as the lawyer would be in designing the utility itself.

Let us have less of precedent, fewer differentiations of rules and dicta, and more horse-sense in valuation work.

Mr. Mayer.

JOSEPH MAYER,* M. AM. SOC. C. E. (by letter).—This admirable paper clears up many of the confusions pervading the discussion of the valuation of public utilities but leaves some points still in a fog which arises mainly from the author's assumption that law and the decisions of Courts, and not justice and the nature of things, are the supreme authority in valuation. Law is but an imperfectly expressed authoritative opinion of the legislature attempting to define justice, and must be and is construed so as to produce justice or such relations among men as will secure the public welfare. The public welfare, and not the Constitution, is the supreme law of every land, as the Romans, the creators of the first great system of laws, already knew.

The author is aware that the idea and nature of value is the foundation of all valuation, but refrains from giving an explicit definition of the idea of value that forms the foundation of his paper. Instead, he gives us a miscellaneous assortment of legal and economic contradictory definitions of value, none of which is quite adequate as a basis for the discussion.

He gives us:

"*Value.*—The sum of the desirable qualities which render a thing useful and sought, measured in money; a measure of the relation of two services growing out of the adjustment of mutual needs."

These are two contradictory definitions. The sum of the desirable qualities which render a thing useful and sought cannot be measured in money because the amount of money which such a sum commands depends on other independent factors. Air is essential to life, and therefore presents a very large sum of desirable qualities, but its value measured in money does not measure this sum. The second part of this definition, which contradicts the first, is more nearly true, because value is a measure of relations between many services, no two of which define value. It is quite indefinite, however, because there are many different relations between services. The value of a thing

* Montreal, Que., Canada.

Mr. Mayer.

or service is a measure of the quantities of many other things it will buy. Money is one of these other things. The quantity of money which can be obtained for a thing is its price. Money at a given time and place has a definite value which can be more easily ascertained than the value of most other things, and its value is more constant in time and space than that of most other things. Therefore, it is the most convenient approximate measure of value. The value of money, however, sometimes fluctuates rapidly; the price of things becomes then a very unreliable measure of their value.

The author also gives us:

"*Market Value.*—The adjustment of two services, *i. e.*, as between a willing seller and a willing buyer under open conditions of competition."

This defines the ratio of the values of the two services which would prevail if competition were universal, but it does not define the competitive value of either; many comparisons are needed to define any kind of value of anything. Since monopolies are spreading, the prices and values which co-exist with monopolies are of most practical importance. If the clause "under open conditions of competition" means simply with competition between many independents, not co-operating buyers and sellers of the two services, then the definition gives the ratio of their values under the given conditions. This ratio it is possible to ascertain if the described conditions actually exist.

Another:

"The sum of money a thing will produce to the seller when sold."

This is the price, not the value.

Another:

"The quantity of labor and capital necessary to produce a given article, or, in other words, the actual cost of its production, is the true criterion of its worth."

This is a clumsy attempt to define the cost of production, not the value. The price of the labor and the interest on the capital used in the production of a thing, together with the profit of the owners and the rent of the land used, with the taxes and other incidental expenses, determine the cost of production, but not the value of a thing which can be produced. Many valuable things, like land and genuine antiquities, cannot now be produced, and therefore have no present cost of production, but they have value.

The author does not state which of these contradictory definitions he believes to be true, and, throughout his paper, does not adhere strictly to any one of them. He has in his mind a much better definition of value, resulting from his wide experience in valuation, which is more nearly correct than any one of those he gives, to which

he generally adheres, and which creates the great value of his paper, but he sometimes abandons it in deference to the Courts, and then he becomes confused and obscure. Mr. Mayer.

The Courts are not authorities on logic. The principles of logic are above the Courts, and demand that the realities must govern all definitions. There are groups of things and groups of phenomena in the external nature; the things or phenomena in each group have certain features in common. These groups are separate from each other; there are few or no transitional forms or phenomena between them. The definitions must draw the lines where Nature has drawn them. True definitions can only be given by those who know thoroughly the things or phenomena they attempt to define. Economists, and not Courts, are most competent to give the true definitions of value which must serve as the basis for valuations. Courts, however, are competent to construe the laws and to decide which values in the possession of individuals can, and which cannot, be taken by the public without compensation. The attempts of the Courts to define values have mostly the purpose to distinguish between these two varieties. It is quite proper to define different varieties of values, but the definitions should describe groups of realities which actually exist in the external world, not only in the mind of the reasoner, and which have real limits that separate them from other groups; and nothing should be called a variety of value which does not belong to the species value.

Court definitions which describe actually existing varieties of value are practically important for valuators, and must be considered in their proper place. The Courts mention fair and reasonable value and fair and reasonable return on the same, without giving definitions of these terms. Their meaning must be inferred by studying the decisions based on them. Until they have been so defined as properly to describe actually existing groups of value which have definite limits separating them from other groups, they cannot be used as the basis of a logical discussion. Beside the nature of value, the laws which govern the changes in values are of the utmost importance in valuation.

Man desires to obtain certain things; he will produce them, if this is the easiest way to get them, and if he likes them more than he dislikes the trouble of producing them. For some things he will make great, for others only small, sacrifices or efforts. The amount of effort or sacrifice he is willing to make, if necessary, to obtain a thing, measures for him its apparent usefulness, and this is the upper limit of the value of the thing for him. The actual value of the thing, as long as he lives alone, is the effort he must make to get it; this is also its cost of production. Things of the same value, under these conditions, have the same cost of production, and things of the same

Mr. Mayer. cost of production have the same value, provided their apparent usefulness is at least equal to their cost of production. The usefulness does not measure value, it only fixes an upper limit which value cannot exceed.

The usefulness may also be defined as the degree in which a thing serves the needs of life. It is, however, not the actual but the apparent usefulness which is measured by the amount of effort one is willing to make to obtain a thing. Things like land, which cannot be produced, can be acquired by effort, and the necessary effort to acquire them measures their value if this does not exceed their usefulness. These are the laws of value, only as long as a man is alone. Other laws prevail where many different men live together and exchange things with each other. If all men were exactly alike and had the same possessions and surroundings there would be no reason for exchanges, and the laws of value above described would also hold for a society of men.

In a society of different men with different possessions and surroundings, the cost of production of the same thing is different for different men. Each will now tend to produce those things or services for which he is best fitted, and will exchange his surplus of these things or services with others to obtain those which he can only produce with great effort or not at all, to the profit of all.

Markets then arise where the prices of things are fixed so that the efficient demand for them equals the supply. The efficient demand for a thing at a given price is the quantity asked for by those willing to pay the price. The supply is the quantity offered. Both change with the price.

The supply of such things as cannot be produced is necessarily not governed by their cost of production, but, if they are owned by many who do not co-operate, it is governed by the prices and by their usefulness to their present owners. If all the owners co-operate, such a quantity only may be put on the market as will bring the largest total price. A small quantity may then bring a larger price than a large one. Where all or most of the producers of a thing co-operate to limit the supply, higher prices are secured than with free competition among many independent producers.

The supply of such things as are produced by many independent, not co-operating, producers, tends to increase when the average profits of their producers are larger than in other productive industries, because capital will flow into the most profitable channels.

Competition is disappearing in many lines of production, and especially so in public utilities. With the disappearance of competition, other laws begin to govern prices and profits.

Without regulation, the prices of the products of monopolized industries are much higher than would be required to secure the same

Mr. Mayer.

average profits as in competitive industries. The difference between monopolized and competitive profits goes largely to promoters and reorganizers of monopolies. Capital invested in unregulated monopolies is generally highly profitable. The promoters and reorganizers obtain the required capital from the public by selling stocks and bonds at prices which bring to the buyers often only about competitive profits. If the consumers of monopolized products organize and fix such prices for them as will give but competitive profits, they can get the required capital from the public, and the prices will be the same as if competition existed. The purpose of the regulation of monopolies is to obtain monopolized products at competitive prices. There are two great difficulties to be overcome in such regulation. The first is to avoid injustice to the present owners of the stocks and bonds of monopolies; the second is that of securing efficiency of management. Valuation is mainly intended to overcome the first; the second, thus far, has been but little considered.

The Courts endeavor to do justice to the owners and the public by giving to the owners a fair return on the present fair value of their property.

The author endeavors to ascertain this fair value of the property of monopolies, and consults for this purpose the Fifth and Fourteenth Amendments of the Constitution of the United States and the decisions of the higher Courts.

The two Amendments prescribe that no State shall deprive any person of life, liberty, or property, without due process of law, and that private property shall not be taken for public use without just compensation. To grasp the meaning of these clauses we must know what is due process of law, in taking private property, and what is just compensation. This we can find by observing closely how private property is taken for the State or Nation. The legislatures are constantly engaged in changing values and thereby taking and giving property to private persons. Legislation might be defined as a process of changing values so as to secure the public welfare thereby. When a tariff law is passed, the values of many goods extensively imported are changed, and with them the values of the factories making them. If States introduce prohibition, the values of breweries and distilleries in these, and to some extent in other, States, are reduced. If a State fixes minimum rates of wages, it changes the value of labor. All tax laws change values and take property. No compensation is ever given by the Courts. It is evident that the Courts either consider these values not to be property, or they believe that no compensation is here just compensation, or that a manufacturer knows, when he enters a protected industry, that the protection may be removed by the legislature and that the value of his plant and the income from it is influenced by this knowledge to such an extent that he receives thereby

Mr. Mayer.

compensation for the risk. This, however, introduces an element of gambling into such industries, which is objectionable. The Courts would probably not sustain this if it were practicable to remove it. These instances are given to show that it does not follow from the Constitution that compensation will always be given where private property, or at least a part of its value, is taken by the State or Nation. They show that the public welfare and the nature of things are the supreme law. The security of property from aggressions by the State, therefore, is not absolute unless all these values are not considered property. It is not important for our purpose whether the values which we consider are or are not property. What is important to know is, which values can and which cannot be taken by the State without compensation. The Constitution gives us no answer to the question. Therefore we must go to the decisions of the Courts in similar cases, and to the principles implied if not expressed in these decisions.

The author has endeavored to find that value which the Courts will award to the public utility companies, and he gives the method he follows in ascertaining it. The variety of value awarded to these companies must be a group having a real existence, and it must be within the species value. All kinds of value are defined as the quantities of other services or things a service or thing will buy; this defines the species value.

Under different conditions, any kind of service will have different values. Varieties of values can only be defined by defining the conditions which influence their value. One variety is that value which exists for the lonesome producer. Another variety exists where there is universal competition, another where unregulated monopolies exist, and many others with regulations of various kinds. The most important condition influencing the value of regulated monopolies is the kind of regulation adopted. The Courts insist that the present value is the fair value to be ascertained. The leading lines of evidence to ascertain the present value are, according to the author, a statement of the earnings and expenses during recent years; the market values of the securities of a property where a broad and representative market exists; the cost of reproduction less depreciation, past cost, and other factors. The Courts and the author neglect to mention the most important factor influencing the present value of a public utility, namely, the kind of regulation to which it is to be submitted in the near future. They are attempting to determine the present value of these utilities as if it were independent of the regulation to be adopted, they practically assert that the value can be determined without knowing what regulation will be adopted. This is a mere legal fiction, in the minds of the author and the judges, which contradicts the facts. There exists no variety or kind of value which

Mr. Mayer.

can be ascertained without knowing all the influential conditions which determine it. To illustrate: The value of an old house is found mainly by estimating the future net revenue which will be obtained by the owner, and estimating the present value of this estimated net revenue; if, however, the value at a near-by future date of the then future net revenue differs largely from the present value of the future net revenue, the former has an influence on the present intrinsic value. The intrinsic value of a house is that value which would prevail if the buyers and sellers would all correctly estimate this future net revenue and the present market value of it, and if they were all governed in their buying and selling by these correct estimates, and by similar estimates for near-by future dates. This intrinsic value the valuator tries to find. It is a definite thing at any time, it does not change rapidly, though the value shown by actual sales may fluctuate widely above and below the intrinsic value. The actual buyers and sellers are governed by more or less erroneous estimates of the future net revenue, based principally on the present net revenue and a consideration of the causes which will change it in the future; they may also consider causes which change the prevailing rate of interest. If the interest rate is rising, the present value of future payments decreases; this reduces the value of the house in the future, other things remaining the same. The knowledge that the value is increasing or decreasing also influences the present value. The buyers and sellers will also consider the ratio between values and net revenues prevailing in the same neighborhood for similar property; they find an approximately constant ratio between the two and then multiply the estimated net revenue by this ratio to obtain the value. If the house considered is out of style and out of harmony with the demands made by the possible buyers of such houses, he will not try to find the cost of production of a similar new house and the depreciation by obsolescence. He will estimate, from the present net revenue and the causes of change, the future net revenue and its present value; or he may ascertain the cost of production (including the cost of land) of a new house adapted to present tastes which gives the same present value of the future net revenue.

To make this clearer, consider the value of a large electric power-plant of, say, 100 000 h.p., with reciprocating steam engines. Such plants are now built much more economically with steam turbines. The value of the old plant is the present value of its future net revenue. The future net revenue depends largely on the future price of power. The price of power, under competitive conditions and without regulation, is mainly governed by its cost of production by the most economical methods known. The cost of a steam turbine power-plant which can obtain the same future net revenue as the old plant with reciprocating engines is approximately the value of this

Mr. Mayer. old plant, because plants giving the same revenue have the same value, and the value of a modern plant is, under competitive conditions, approximately equal to its cost of production. It would be most absurd to attempt to find the depreciated value of the old plant by finding first the cost of reproduction new of a similar plant and then the difference between this cost and the value of the old plant. The similar new plant would be antiquated, and its cost of production does not indicate its value. Its value could only be found by ascertaining the cost of production of a modern plant bringing a future net revenue of the same value. After this the values of the antiquated new and the antiquated old plant would have to be compared by comparing the present values of their future net revenues. Since the cost of reproduction new has no influence on the value of an antiquated plant, it is a waste of time and money to determine it. The cost of reproduction new of an old antiquated plant, therefore, is absolutely worthless as an evidence of value. In all cases where obsolescence is an important factor, the only rational method of finding the value is by comparison with the cost of production of an equally valuable modern plant, or one producing a future net revenue of equal present value. Any cost of production, however, is only under competitive conditions an approximate measure of value. Where monopolies prevail, the cost of production does not measure the value. With regulated monopolies, the value depends mainly on the kind of regulation adopted. As the author states, the value of a well designed plant meeting the needs of a growing market is at least equal to the cost of production under any kind of practicable regulation; but the value may be much more with the existing methods of regulation. The recent net earnings are only a leading evidence of value when they indicate the probable future net earnings; this they do only if the regulation in the future is the same in its effect on the value as that in the recent past.

The author in his method of valuation practically assumes that this regulation will be the same in its effects on value as the regulation of the recent past; therefore he believes that the fair value of a public utility is that value which exists if the future regulation produces the same values of the present properties as that in force in the recent past; and he consistently follows this definition, except where he is compelled by deference to the Courts, for the purpose of obtaining their approval for his valuations, to deviate from it. As the author states, the Courts are very cautious, and cannot be induced to commit themselves to wide generalization; this is the function of the legislatures, not of the Courts, and the latter should give a clear definition of the fair value of utility companies; then they could be valued by ordinary business methods of valuation without insisting on the

exact ascertainment of the value of the carcass for the purpose of obtaining the value of a live horse. Mr. Mayer.

The author says that valuation consists in collecting the facts influencing value and in judging them. He is practically compelled to omit the most important fact—the future regulation—and he can only describe superficially the various operations to be performed in the judging, but he cannot find a real method of judging without first, implicitly, if not expressly, assuming what kind of value he desires to ascertain. A clear idea of what you want to ascertain is absolutely necessary for finding the methods of ascertaining it. The present value of public utilities is very nearly identical with the value which would prevail if the future regulation were the same as the present one. Substantial justice, or as close an approach to justice as practicable, would be done to the present owners of the securities of these corporations if their value were ascertained with this assumption, and if a fair return on this value would be paid to the stockholders. This, however, must not be decided by the sense of justice of any one, or any class of individuals, but by the will of the whole community expressed by the legislatures or the Courts. Most of the conflict of opinion in the discussion of valuation arises from conflicting ideas of justice. With universal competition, fair prices and values rise, if each producer is left free to offer his products at whatever price he pleases. Under such conditions the average profits in all industries tend toward equality, therefore the idea arose that justice requires that each should be free to choose the prices at which he is willing to sell or buy. After natural and artificial monopolies became numerous and important, this absolute freedom of action did not any more produce just prices; the old ideas of justice, however, were for a long time enforced by the Courts and legislatures, and great injustice in the distribution of income and wealth resulted therefrom. This brought about a conviction that such absolute freedom cannot be allowed, and efforts were made by the legislatures, the Courts and the, for this purpose created, public utility commissions, to establish just prices. Under the old laws very large returns on the invested capital were secured in the monopolized industries, and their value, therefore, often largely exceeded their cost of production. Whether the values of monopolies created under the mixture of freedom and regulation of the recent past shall belong to the owners of the corporations or partly to the public is still unsettled. Similar changes of conditions and of prevailing ideas of justice characterize all historical development, as is shown by Henry Sumner Maine.* He says, in his chapter entitled "Legal Fictions":

"In progressive societies social necessities and social opinion are always more or less in advance of law. We may come indefinitely

* "Ancient Laws."

Mr. Mayer.

near to the closing of the gap between them, but it has a constant tendency to reopen. Law is stable and some societies progress. The greater or less happiness of a people depends on the degree of promptitude with which the gulf is narrowed."

Much of the difficulty in valuation arises from the insistence of the Courts on their legal fiction that it is possible to find the value of a regulated public utility company without knowing the nature of the regulation. This necessitates the abandonment of the only correct and reasonably accurate business men's method of finding the value of a public utility company by estimating the present value of its future net earnings; and forces the adoption of some artificial and extremely complicated substitute that pretends to find its value without considering the regulation, and that is nevertheless compelled to assume implicitly a definite kind of regulation, as it is quite impossible to solve the problem in any other way. No agreement on questions of valuation is possible until either the Courts change their course or the legislatures settle the question by statute law.

Another important legal term requiring a clear definition is "a fair return". For the stockholder of public utility companies, this is just as important as the meaning of "fair value", unless he is offered cash payment for the fair value of his property. It makes an enormous difference whether 5 or 8% is considered a fair return, and this should not be left to individual judgment, or merely guessed at, but should be determined on such known general principles that the investors can foresee the decision. There is substantial agreement, however, that a fair return for any monopolized industry is the same return on its value as is obtained in competitive industries, or a return just large enough to obtain the necessary capital; but there are individualists and socialists defending two radically different methods of distributing the profits of a monopolized industry among the different enterprises engaged in it. The individualists say the regulation should be such that the profits in every enterprise will be the same as they would be if competition existed. With free competition the profit in every individual enterprise is different; some bring large dividends, some go into receivers' hands, some are entirely abandoned on account of changes in the arts, but the average rate of profit in every industry at the same place and time tends to be the same. There are differences of average profit at different times and places. In a very new country, profits are larger than in the East. The average rates of profit at different times and places vary mainly with the rate of interest, and they are often larger in growing than in decaying industries. To bring about such a condition of things in the monopolized industries, it would be necessary to ascertain the average rate of profit in competitive industries and to establish such prices of monopolized products as will produce in each monopolized industry the

same average rate of profit as in the competitive industries at the same time and place, with slight variations to bring about the needed increase or decrease of supply. The prices of gas and electricity, the street car fares, etc., would have to be different in different places. The differences would have to be equal to the differences in cost of production with ordinary methods of production, as is approximately the case in competitive industries. The profits of the different enterprises would then depend mainly on the efficiency of management, or the amount of intelligence, conscience, and energy put into each enterprise, and the same inducements to secure efficiency would exist as with free competition. Mr. Mayer.

The writer has roughly sketched such a regulation in a previous paper.*

The public utility companies may endeavor in their regulations to approach this ideal of different profits in proportion to efficiency of management, or they may set before themselves another ideal, namely, equal profits in all enterprises, large enough to secure the necessary capital for increases of plant. If this latter ideal were followed consistently the stockholder would have no pecuniary inducement to select efficient directors, and the directors chosen would have none to obtain efficient management; or to adopt the most judicious salaries and wages for all the employees and to employ the best men obtainable for them; or to watch the performance of every one and to advance them for merit only; or to study all proposed improvements and to adopt them quickly if meritorious. All these things would have to be obtained through the supervision of the public utility commissions. The directors would become useless puppets, and they would soon be discarded as an unnecessary incumbrance. If the ideal were followed consistently, the stockholders would become practically bondholders, and money could be obtained at a moderate rate of interest, either by the sale of nominal stock or of bonds. The risk would be carried by the public, and the management would become entirely responsible to the public instead of to the stockholders. The public would become the virtual proprietor at the moment the ideal was adopted and consistently followed. Good results can be obtained by public ownership with public management, but not by public ownership and risk with private management.

This ideal of regulation is not yet followed consistently by the Courts and the public utility commissions, but they are gradually being compelled to adopt it by the manner of fixing the prices of monopolized products.

The consumers or one or more of the utility companies complain that the prices are too high or too low. A Court or a public utility

* "The Just Value of Monopolies, and the Regulation of the Prices of Their Products", *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 455.

Mr. Mayer.

commission is requested to fix fair prices. They proceed to value the property by some extremely artificial and therefore inaccurate method, which must hide the fact that some kind of regulation is necessarily assumed in the valuation. After the valuation is obtained, a rate of profit is fixed which is believed to be just adequate to secure the necessary capital for extensions, and the prices are adjusted to produce this rate of profit. The risks of investments in controlled public utilities are peculiar and entirely different from those in competitive enterprises. Therefore it is very uncertain what rate of profit will make it possible to obtain the necessary capital for extensions. The Courts generally let a master decide this knotty question; the public utility companies guess at it themselves, as this is the best they can do under the circumstances. To fix a just rate of return for average efficiency of management, it would be necessary to ascertain the average rate of return in competitive enterprises and to create such conditions for the monopolized industry that the risks of capital are the same as with free competition. To do this to settle an individual dispute is impossible. An intelligent guess is therefore the best practicable solution of the problem. The commission or Court would undoubtedly fix a lower rate of profit where they find legal evidence of gross inefficiency or dishonesty, or might reduce grossly excessive salaries, but, for most of the factors which really govern the efficiency of management, no legal evidence can be presented to the Courts or commissions, and therefore they cannot be considered; but, even where such factors are legally known, it is impossible by the available machinery to calculate or estimate correctly the amount of change in cost of production caused by them and to allow for it by a different rate of profit.

The purely mental qualities of intelligence, honesty, skill, and energy, which cause such large differences in the cost of production of the same goods, selling at the same prices in competitive industries, and consequent large differences in profit, cannot be directly measured; they can only be judged by the material effects they produce. The Courts and commissions, by the now prevalent methods of fixing prices of monopolized products, are practically compelled to ignore all differences in such mental qualities which cannot be measured by their method of procedure, and to award equal profits to all enterprises, or equal compensation to intelligence, honesty, skill, and energy, and to stupidity, dishonesty, incompetence, and laziness. The Courts are established to settle individual disputes, and they cannot deviate from their usual method of considering each dispute separately from all the others. The utility commissions must either abandon this method, by creating such just systems of prices as would prevail if free and fair competition did exist; or they must obtain the capital for monopolized industries at a fixed and consequently low rate of

interest; and they must manage these enterprises themselves, discarding the private boards of directors elected by stockholders. Until one of these alternatives is chosen, increasing inefficiency and expensive capital with consequent high prices are inevitable. Statute law must decide which of these alternatives should be chosen for the different monopolized industries. Mr. Mayer.

PHILIP BURGESS,* M. AM. SOC. C. E. (by letter).—The writer has read this paper with great interest. It is a very timely and valuable contribution to the literature on the subject, and will be appreciated by any one interested in the matter, and especially by any one who has had occasion to follow through a particular case, as developed by hearings before a Court or commission. That members of the Engineering Profession frequently do not have a clear conception of the fundamental principles involved in the subject is very apparent from their testimony before Courts and from their discussions of papers, as printed in the publications of this Society. Such differences of opinion can be accounted for only by the fact that engineers have not taken the time, or have not had the ability, or opportunity, to acquaint themselves with the present status of the subject of the valuation of utility properties, as determined by decisions of the Courts. It is apparent, moreover, in many instances, as indicated by Mr. Alvord, that engineers frequently appear to know more about the subject than do the Courts, a position which, of course, leaves the witnesses open to severe criticism, or even to ridicule, and has a tendency to lessen the value of all expert testimony, even when given by qualified witnesses. This has undoubtedly called forth the frequently cited remark by a Court to the effect that expert testimony is the most unsatisfactory of all evidence. Fortunately, this criticism is not confined to engineers. Mr. Burgess.

The writer has had the pleasure of listening to Mr. Alvord's testimony when on the witness stand for several days, and has been much interested and impressed by the fact that he always has had a clear conception of the matter at hand, as he saw it, and has always started with some fundamental conception of the principle involved, and then has endeavored to follow this conception through to a logical conclusion. It is undoubtedly true that there is no subject before the engineer to-day which requires so clear a conception of the fundamental principle involved as does the appraisal of properties devoted to public use.

One instance may be cited to show how much the value of the testimony of an engineer may be weakened unless he has a clear conception of these principles. In a water-rate case, in which the writer was interested, a certain witness for the utility—who is a member of this Society—submitted a report on the cost of reproduction

* Columbus, Ohio.

Mr. Burgess.

new of the properties in question, and, when the report was handed in as evidence, stated that he did not know whether or not the cost of cutting through pavements over pipe lines should be included, and that such cost was not included in the report. Subsequently, Mr. Alvord, also called in by the company as a witness, stated why, in his opinion, the cost of cutting through pavements should be included. Later, the first witness asked to be allowed to state that he now believed that the cost of cutting through pavements should be included.

Under such circumstances, one can but ask the question as to whether or not the witness would have made up his mind on such an important item so quickly had he been on the other side of the table. It is very apparent that the witness did not have a clear conception of the fundamental principles involved, or that he was prejudiced.

Such instances of disputed items, whereon, perhaps, the Courts have not given deciding opinions, arise in all cases of valuation. It seems to the writer that, unless the engineer wants to appear in an unfavorable light, he must have a logical reason for arriving at his conclusions in all matters pertaining to the case, or he must state that "he does not know". He may well qualify such a statement to the effect that the matter is a legal and not an engineering question, and in fact is one for the Court itself to determine. If the Court decides that the item in question is a proper one to include, the amount may be stated to be so much. The point as to whether or not the item is a fair one to include may far better be argued by the attorneys in the case than by the engineering witness.

Doubtless one of the most valuable features of Mr. Alvord's paper will be found to be the legal citations and references with which, of course, any engineer who pretends to qualify for appraisement work should be familiar.

Mr. Alvord has indicated, in characteristically clear language, the four fundamental lines of evidence to be considered in making an appraisement. These are: (1) the cost of reproduction new; (2) the market value of securities of the company; (3) the comparative value of similar properties; and (4) the past costs of the properties in question. The writer believes that he is warranted in assuming that the importance of each of these items, in the author's opinion, is indicated by the order in which they are placed. In fact, in two instances in water-rate cases wherein the author and the writer have been jointly interested, although on opposite sides, the author has been contented to adopt his conclusion, as reached by investigations of the cost of reproduction new, without any apparent investigation into the actual past cost of the properties or of many items comprising them.

Mr. Alvord's paper may be considered as a very able argument, or demonstration, of the value of the cost of reproduction new as the foremost line of evidence to be considered in arriving at the value of public utility properties, especially if we include his qualifications of such costs new as indicated in his fourth line of evidence to be considered, namely, the relations of the utility to the consumer, the value of the service to the consumer, and the general business status of the properties. Mr. Burgess.

It would also seem to be apparent that Mr. Alvord is very much disappointed that some appraisers have seen fit to give so much value to such evidence as past cost of the properties. As the author very well states: "What does it profit us to discuss the details when this serious and fundamental difference exists?" The writer believes that, after all, except in the case of extremists, there is not so much difference of opinion among appraisers who are well informed in the matter as would at first appear.

As stated in the paper:

"The function of valuing a public utility property consists essentially of two distinct operations:

First.—The collection of all facts and evidence tending to throw light on the question of value."

It cannot be disputed that the best evidence as to the cost of the many items composing the properties in question is to be found in the books of the company. It is not denied that the conditions of construction may be different to-day from what they were when the plant was constructed. Nevertheless, the actual past costs, especially of particular or individual component parts of the plant, are facts, and are always of interest and value to Courts and appraisers. Such facts may very well be considered by appraisers, even in developing evidence or opinions along the lines of reproduction new, as of to-day. In this connection, it is necessary to consider what are the apparent differences between the conditions under which construction must take place to-day, as compared with those under which construction actually took place in the past; also, how such conditions affect costs.

As a matter of fact, it seems to the writer that the cost of reproduction new method of valuing properties is largely, if not wholly, a comparative method. There is, of course, no intention of actually constructing new properties exactly like those in question, but the appraiser must consider all evidence which may throw light on the probable sum that would be required to construct such a new comparative plant. A determination of the cost of reproduction new is essentially a matter of detail, comprising determinations of the probable cost of reproducing new many items, or component parts, of the comparative plant. Although it is true that comparative costs of other properties or units and estimated costs new of the

Mr. Burgess.

comparative plant by contractors or by engineers are all valuable aids to the appraiser in arriving at the probable cost of reproduction, it seems to the writer that unquestionably the actual past costs of the properties or units in question, as shown on the books of the company, are the best evidence for the appraiser by which to estimate the cost of reproduction new, provided, of course, that he considers and allows for all comparative conditions of construction between the past and the present.

Doubtless this is why appraisers, in many instances, have considered the past costs of new properties to be the best evidence as to their present value, because, of course, it is recognized that, in comparatively new properties, the conditions of construction under which the so-called comparative plant may be built are similar to those under which the properties in question actually were constructed. With older properties, however, this is not generally true, and it is on the older properties that there will be greater differences of opinion as to present value on account of this difference between the past cost method and that of reproduction new.

There are, however, certain very material differences in the appraisal values which may be obtained by using the past cost and the cost new as of to-day. These apply both to tangible and intangible costs.

Among the costs of tangible property included in reproduction and not in past costs are such items as the costs of cutting through pavements over mains and services—pavements which were constructed subsequent to the laying of the pipes. Such costs do not appear on the books of the company, but, if we are to reproduce the existing properties as of to-day and under present conditions, the costs of cutting through existing pavements is an element of the cost of reproducing the properties as of to-day. In the same way, in estimating preliminary costs, such as engineering, superintendence, interest during construction, and others, there will also be a difference between the amounts estimated for the cost of reproducing the properties and that actually incurred during the construction of the existing plant. Preliminary costs which may be entailed by the construction new of the comparative plant are purely matters of opinion based on facts and the knowledge of the appraiser as to such comparative costs of similar properties. They are estimated as an aliquot part of the complete plant as of to-day. The actual preliminary costs incident to the construction of the existing properties appear on the books of the company, and, of course, are a similar part, or proportion, but of a much less valuable property. Consequently, preliminary costs based on past costs almost invariably will be less than preliminary costs as estimated for the construction new of the comparative plant. This is because such overhead costs as engineering and general supervision

frequently are paid for entirely out of earnings during recent years and do not appear in the plant account. Mr. Burgess.

In the same way, there is frequently a marked difference between the results obtained by considering the two lines of evidence in determining intangible values, such as going value. The past cost method requires consideration of the actual revenues and operating expenses entailed by the plant during its early history. By some appraisers, this method is carried further to a consideration of whether or not early deficits have been compensated by subsequent earnings of the properties. By the comparative method, however, it is necessary to consider the earnings and expenses of the existing plant during recent years and to project these into the future with a view of determining the probable receipts and expenditures of the comparative plant, the construction of which is conceived to begin on the date of making the appraisal. Here again we have two lines of evidence, the one based on past costs, the other on the future, or present cost of developing the business of the so-called comparative plant. It is only an accident if they agree as to the result. Of course, going value, under the comparative or reproduction method, never can be negative, or compensated. So long as the properties are earning they have a going value.

On account of the many past appreciations and depreciations of the several component parts comprising the properties, none of which changes in value appears on the books of the company, but all of which do enter into the cost of reproduction new as of to-day, it is apparent that, in most instances, there will be considerable differences in the net results as obtained by using past costs and costs of reproduction new in estimating the value of utility properties, especially in the case of utilities which have been rendering service for comparatively long periods of time. As previously stated, however, it is the writer's belief that there need not be very great differences of opinion among appraisers as to the net results obtained in valuing a particular property, especially if we recognize the fact that the cost of reproduction new, though a most valuable line of evidence, is not the only line to be considered. That it is not the only line of evidence to be considered is well indicated by the Supreme Court of the United States in the Minnesota Rate Case, as follows:

"The cost of reproduction method is of service in ascertaining the present value of the plant, when it is reasonably applied and when the cost of reproducing the property may be ascertained with a proper degree of certainty. But it does not justify the acceptance of results which depend upon mere conjecture. It is fundamental that the judicial power to declare legislative action invalid upon constitutional grounds is to be exercised only in clear cases. The constitutional invalidity must be manifest, and if it rests upon disputed questions of fact the invalidating facts must be proved. And this is true of asserted value as of other facts."

Mr. Burgess.

In the writer's opinion, it is difficult to see how any appraiser can have at hand more relevant facts than the figures which appear on the books of the company as indicating actual past costs, especially of new properties. It must be considered that, in any particular instance, the only additional facts available are the costs of other properties generally similar in character to those in question, but, of course, not identical with them. It is the writer's belief, therefore, that, after all, there is not so very much difference of opinion among well informed appraisers as would at first appear. The cost of reproduction new is of very great value, but is not by any means the only line of evidence to be considered in arriving at the present value of properties devoted to public use. Past costs always will be considered, both of themselves, and also in determining the cost of reproduction new of the comparative plant, the conceptional construction of which is necessary in determining reproduction costs as of to-day. It must be admitted that the reproduction new method involves largely questions of opinion which are evolved from the consideration of all relevant facts. The past cost method, however, is purely a question of fact. That is the fundamental difference between the two methods.

The writer does not wish to be misunderstood as advocating the promiscuous intermingling of past and present costs in arriving at the fair present value of a property. This is, perhaps, the most frequent error that is to be found in utility appraisements. He simply wishes to emphasize the value of past costs, especially of the component parts of the properties, as the best evidence which may be obtained to determine the present costs of reproduction new. From past costs of units, where available, one may very well reason to present costs. Without such past costs, all evidence of present cost is purely comparative, and, consequently, is a matter largely of opinion. Therefore, it is open to more or less serious objection or criticism, in so far as it approaches the realm of conjecture.

In conclusion, the writer believes that engineers must accept and adopt the position, so well argued by Mr. Alvord, that cost of reproduction new, as of to-day, is a principal line of evidence to be investigated in all appraisals of properties devoted to public use. He wishes to emphasize the fact, however, that this is not the only line of evidence to be considered, and that past costs, especially of recently constructed properties, afford the best evidence as to the cost new of many items which enter into the estimated cost of reproduction, as of to-day. Past costs of entire properties generally are not available, and, where they are available, may be very misleading if used to determine "the fair present value of the property used and useful to the public."

PAPERS AND DISCUSSIONS

This Society is not responsible for any statement made or opinion expressed in its publications.

THE LOCK 12 DEVELOPMENT OF THE ALABAMA POWER COMPANY, COOSA RIVER, ALABAMA.

Discussion.*

BY MESSRS. JAMES H. HARLOW, R. D. COOMBS, HUGH L. COOPER, HEINRICH HOMBERGER, H. BIRCHARD TAYLOR, SPENCER MILLER, AND W. E. MITCHELL.

Mr. Harlow.

JAMES H. HARLOW,† M. AM. SOC. C. E. (by letter).—Like most writers of technical papers, the authors fail to describe the plant constructed so as to permit the reader to answer the question "Will it pay?" This is the question uppermost in the minds of those to whom we go for funds with which to carry out our ideas. It involves two other questions, *viz.*, the cost of the plant under consideration, and the character and extent of the market for the power to be developed.

The writer finds one stock objection to the construction of a hydro-electric plant, and that is, "a steam plant can be built for much less, and the best turbo-generators can be operated on 20 lb. of steam per kw-hr." Several times when this statement has been investigated, it has been found that 20 lb. of steam did not include the auxiliaries, and instead of 20 lb., it was nearer 30 lb.

The writer is interested in several hydro-electric plants, and, when the stream will give power for 9 months per year and for the other 3 months the plant is operated by steam, the resulting power is produced more cheaply than by steam alone.

A year has passed since the construction of the Lock 12 Development, and some interesting facts must have accumulated in the opera-

* This discussion (of the paper by E. L. Sayers and A. C. Polk, Members, Am. Soc. C. E., published in September, 1914, *Proceedings*, and presented at the meeting of November 4th, 1914), is printed in *Proceedings*, in order that the views expressed may be brought before all members for further discussion.

† Darlington, Md.

Mr. Harlow.

tion of the plant. The authors will supplement the paper, perhaps, by answering the question, "Has it paid?"

What was the cost (ready to operate) of the hydro-electric plant per kilowatt on the station switch-board?

What was the cost of the steam auxiliary plant per kilowatt on the station switch-board?

(The cost per kilowatt should be based on the actual annual output of each plant.)

What was the actual output of each on the switch-board?

The greater the detail of the costs, the more value it will afford to designing and operating engineers.

Another point of interest is the size of the units. The authors say, "The adoption of this size of installation was dependent on many factors and a number of assumptions, * * *." May we hear further on this point later?

The writer has knowledge of a plant designed to adopt units of 37 500 kw. Are we not trying to follow a fetich in these large units?

From some of the writer's investigations, there is a point in the cost of generators where the cost per unit of output rises. Is not the cost of the combined hydraulic and electric machinery a rather small part of the total development cost, and should it be followed as far as we seem inclined?

At the plant in question, can more than one unit be operated at the extreme low-water flow, and if two must be run to get the use of all the water flowing, is not the efficiency being reduced much below that expected?

The highest efficiency is in demand at times of low water; when there is plenty of water, efficiency is not so necessary. The writer has demanded that the highest efficiency shall be at about from 75 to 80% of gate-opening. Turbines cannot be well regulated when operating at near full gate.

How are the authors going to determine whether or not the "guaranteed efficiency" is obtained? They certainly do not depend on the Holyoke tests of a (comparatively) small turbine and then the guess of the builder that the full-sized turbine will "fill the bill."

The best hydraulic tests are probably not within several per cent. of the truth. Do we know enough about the "chemical test" to be sure we know the exact efficiency?

Horizontal vs. Vertical Units.—Unless the tail-water rise is in excess of the suction effect, why was the vertical unit adopted instead of the horizontal?

Some years ago we required our steam turbo-generators to swing on a vertical axis, but now we are going to the horizontal.

The hydro-generator is now going toward the vertical; shall we, after a while, swing back to the horizontal?

Mr. Harlow.

The McCall's Ferry plant has been referred to as using the vertical type, but here the tail-water rise may be as much as 35 ft., and it must be remembered that the third thrust-bearing is being tried, and successfully thus far; but it took the third trial to get the bearing. A longer trial may change our views.

Papers like this are valuable, but more attention should be given to "will it pay" or "does it pay," and to do this we must have details of the costs as well as of the construction.

Mr. Coombs.

R. D. COOMBS,* M. AM. SOC. C. E.—As it is the avowed purpose of the authors to bring out discussion on the latest ideas and methods relating to hydro-electric power plants, including those pertaining to transmission line construction, the speaker will confine himself to a discussion of, and perhaps some additions to, the methods described in the paper.

Unfortunately, the authors have followed the usual practice and dismissed the subject of line construction in a very sketchy way. The word "unfortunate" is used advisedly, as the subject merits more consideration.

Apart from the real need of more literature on this subject, in order that future work may have the benefit of past experience, it would seem that the sole link connecting the expensive power-generating station with the consumer should be considered of relatively greater importance.

In addition to the two foregoing considerations, the speaker believes that the comparative importance of the line, from an economic standpoint, has usually been partly disregarded. As the entire installation is a commercial enterprise, the income of which is derived from the sale of the current carried by the transmission lines to the purchasers, the lines themselves may be a large factor in the possible quantity of unproductive, expense-bearing time. In other words, the connecting link may cause stoppages in the sale of current, and, in extreme cases, render the entire installation unproductive for various periods of time. Therefore, the maximum possible security from interruptions to service, obtainable with a reasonable expenditure, is very desirable in any line installation.

The transmission lines—and in this discussion no special distinction will be made between so-called transmission and distribution lines—may be of two general classes: aerial open wires and underground insulated wires or duct lines. The latter are approximately three times as expensive to build as the former, and as they have but few applications in hydro-electric development, in the United States, may be omitted from consideration herein.

In reviewing the data in the paper, it will be noted that in general the design appears to follow the latest methods of wide-base tower

* New York City.

Mr. Coombs.

construction. These are—to give them in outline—long spans, stranded cable, overhead ground wires, vertical spacing, and staggered middle cross-arms. Unfortunately, information is lacking as to the details of construction, and the reasons for various decisions as to such details.

Referring to the lengths given for the two kinds of cross-arms, it would seem that there must be an error in the stated length of the middle arm, because, as given, it only offsets the wires 9 in. This small offset, which is introduced in such lines in order to minimize the probability of wires sagging, falling, or blowing into contact with each other, is inadequate for the purpose.

It is stated that the Type A towers, which are 68 ft. high, were used in rough country with standard spans of 700 ft., and that Type C towers, 65 ft. high, were used in flat country, with standard spans of 600 ft. Unless the towers could be located in an almost miraculously favorable manner, the speaker believes that this relation would not obtain, because rough country ordinarily compels the use of spans shorter than standard, unless the towers are made higher. This is due to the constant need of decreasing the sag in order to maintain the required clearance of the wires above the ground.

Although not thus stated, the inference may be made that the design, as well as the clearance, was based on a loading of $\frac{1}{4}$ in. of ice and 8 lb. of wind pressure. The speaker believes that a loading of $\frac{1}{2}$ in. of ice and a wind pressure of less than 8 lb. is better general practice. Some reduction from the latter loading may be justified in certain cases, particularly in construction with very long spans, but the speaker believes that in actual practice it will be the wind pressure, rather than the ice, which will be reduced. However, in the case in question, it may perhaps be argued that a large accumulation of sleet need not be expected on 110 000-volt wires while alive, and that the period during which the wires will be dead would reduce the probability of the maximum load to a negligible quantity. It would be of interest if further explanation were given in regard to the relative strength of the towers in the standard spans, and in the maximum spans mentioned. Ordinarily, such maximum spans are of rare occurrence, and they are frequently guyed in order to withstand the heavier loads.

Although no particular criticism may justly be made of the main transmission line, as it fairly represents one of the two best types of construction, there may be some difference of opinion as to its relative advantage as compared with two one-circuit pole or tower lines. The so-called distribution line, of 22 000 volts, on wood poles, however, is not of as excellent construction, and, if its location is permanent, a steel pole line would perhaps have been justified instead.

As steel pole lines, such as those shown by Fig. 54, with spans

FIG. 54.—TWO-CIRCUIT STEEL POLE LINE.

of medium length, are growing in favor for 22 000-volt transmission lines, they are worthy of consideration for a 22 000-volt distribution line. The size of the conductors in the 22 000-volt line is not stated, and a photograph is an uncertain basis for measurement, but the pole spacing of 175 ft. and the vertical and horizontal spacing of the conductors do not appear to be consistent. Mr. Coombs.

HUGH L. COOPER, M. AM. SOC. C. E.—The cross-section of the wheel setting, Fig. 11, shows that the thrust-bearing is carried on top of the generator frame. It would be interesting to know the experience with the thrust-bearings at this plant, particularly with reference to their ability to carry the load without interruption. The speaker has been informed recently that, in operating under conditions approximating full load, these bearings have given trouble. Mr. Cooper.

These Kingsbury bearings have been used with much success in the plant of the Mississippi River Power Company, at Keokuk, and the speaker believes that they are, undoubtedly, the coming bearings for vertical shafts with heavy loads, provided they are supported properly. Exact data regarding any trouble with this bearing at the Coosa plant would be valuable. On more than one occasion the proper location of the thrust-bearing on the shaft has been under discussion. Some have been of the opinion that such bearings can be supported on long metal spans and run successfully; others hold that they should never be placed in that way, but should be supported on a non-elastic foundation—the firmer the better. Specific and correct data on this subject will be of much value in designs for future work of this kind.

In reference to the pit liner, Fig. 13, will the authors state whether or not the castings were machined after they were set in concrete? The speaker has always found that the shrinkage of the concrete threw the casting out of line, no matter how well it was milled in the shop. On the work at Keokuk the pit liners were set with the greatest possible care, using specially designed leveling jacks, and notwithstanding the great weight and stiffness of these liners, there was a considerable change in the alignment after the concrete had set. This could not be neglected, and therefore the main bearing surfaces were milled *in situ*.

HEINRICH HOMBERGER,* M. AM. SOC. C. E. (by letter).—This very interesting paper is without doubt one of the most valuable additions to the literature on large, low-head, hydro-electric developments of the most recent type. Mr. Homberger.

In reference to the turbines, the authors state that one of their features is that they are "self-contained." With first-class design, vertical-shaft turbines of this particular type, of such huge dimensions, could hardly be otherwise; each, of necessity, must be a homogeneous

* Mill Valley, Cal.

Mr. Homberger.

structure, or it would be impossible to make a satisfactory job of the installation in the plant. It is hardly possible to believe that any modern manufacturer would contemplate building such a turbine without setting it up completely in the shop before shipment to the plant, and, in order to clear up what the writers had in their minds, it would be interesting to note what character of "very expensive machine work is commonly done in the field" with turbines of the size and type described.

The turbine runner is fastened to the shaft with a taper fit. This is very expensive work if thoroughly well executed. A taper fit has the advantage that the joint may be readily broken, which is of importance where the hub is to be removed from the shaft frequently. This is hardly expected to be the case with a turbine runner. If a parallel press fit is selected instead, it has the advantage that the runner can be driven home to a fixed point and its location is absolutely determined. Of course, there is no leeway in the location of the runner on the shaft, and to make the taper fit a success, it is generally necessary to press the runner on and off the shaft many times, with intermediate scrapings, until the hub is exactly in its right position on the shaft and at the same time comes to a perfect bearing thereon. It seems that the taper fit is rather a design borrowed from marine practice and used for fastening a propeller to the tail-shaft. Propellers are likely to have to be replaced much more often than turbine runners, and the exact location in the axial direction of the shaft is of no importance. It is sufficient to scrape the propeller hub to a fit on the shaft and then tighten the nut.

With reference to the efficiencies which have been guaranteed: Supposing that the generator was expected to operate on a 75% power factor, this would allow about 25% over-load capacity in the turbine. It is common practice to select the point of highest efficiency at about three-quarters of the capacity of the turbine, which would be somewhat below the rated capacity of the generator, because, at a plant with several units, the machines are expected to operate normally at about the rated capacity of the generator. With the Alabama turbines, the highest point of efficiency appears to have been very near the full capacity of the turbine (the exact point is not given), and it is very rarely expected that the turbine will operate under such a heavy load; in reality, it would probably be operated mostly near 14 000 h.p. output where the efficiency is 4% lower than the guaranteed maximum.

The question of the value of Holyoke tests compared with field tests after installation has been thrashed out frequently, and the writer was pleased to see how much stress the authors have laid on the necessity of checking up the Holyoke results by actual field tests. Although Holyoke tests are very interesting to the designer of turbines,

Mr. Homberger.

they give an insight only into the characteristics of the turbine runner and its behavior under varying conditions; all the other accessories which make up the complete turbine, and the general mechanical and hydraulic conditions of the setting, which greatly influence the efficiency, cannot receive any consideration at the testing flume.

The question whether preference should be given to vertical or horizontal units has been argued, and the selection of the former is explained by stating that horizontal units would promise not as high an efficiency on account of the necessity of sharp bends in the draft-chest, causing loss of head, and that there were other losses from the confluence of streams in the draft-tubes of multi-runner horizontal units.

To the writer, it does not seem necessary to make the curvature of the draft-chest of a single-discharge horizontal turbine of any smaller radius than the draft-chest of a vertical unit. Referring to Fig. 7, which shows the draft-elbow as constructed in concrete masonry, exactly the same curvature could have been chosen for a single-runner, single-discharge turbine with horizontal shaft. As far as space is concerned, if the units were arranged athwart the power-house, the greater part of the draft-chest could be embodied in the power-house substructure, and the length of the power-house would not have to be increased. If such a unit had been selected for the Lock 12 Development as described, considering the very large capacity of the units, it would probably have developed into a two-bearing independent turbine coupled to a two-bearing engine-type generator. It might have been advantageous to combine generator and turbine into a three-bearing unit with one continuous shaft, requiring a narrower power-house. In either case, although horizontal machines would have required a wider building, the foundations would have been very much simpler than they necessarily had to be for vertical units; and a comparison of costs of the two types of power-house building would be interesting to the profession. Doubtless such a comparison was made by the engineers of the power company before units of the vertical type were adopted.

One of the prime advantages of the horizontal-shaft unit is its greater accessibility and the greater ease with which the turbine may be dismantled. In the natural course of events, turbine runners of any type of unit are bound to wear, and must be replaced sooner or later. With a horizontal shaft and a scroll casing built up of a number of parts, the removal and replacement of a runner is much easier and much less costly, and takes a great deal less time than with a vertical-type unit where the entire stationary superstructure of the generator, the exciter, the thrust-bearing, the steady-bearing, the gate rigging, and the entire rotating part of the unit have to be dismantled before the turbine runner may be removed from the shaft and replaced by a new one.

Mr. Homberger.

Highest efficiencies and economic construction may well be attained with volute or scroll casings of large horizontal shaft units, as recent practice both in the United States and in Europe has proved.

It does not seem impossible to the writer to design a horizontal, single-runner, single-discharge unit for the conditions as they are in the Lock 12 Development and to obtain satisfactory structural features throughout.

With reference to "loss from the confluence of streams in the draft-tubes in multitudinal units", this does not seem to apply in the present case. If a single-runner, double-discharge unit had been chosen, these losses could have been avoided by arranging for two draft-tubes, and there would have been no confluence of streams. The question of installing units of the double-discharge and single-runner, or double-discharge double-runner type, had probably been examined to a considerable extent when the hydraulic equipment of the plant was under discussion. There could also have been selected a unit with two scroll casings, one for each runner, which would have promised a very high efficiency. This type of unit has become well known to the profession since the power-plant of the Ontario Power Company at Niagara Falls was started, about a decade ago. The prime advantage of this type of machinery would have been the possibility of selecting a turning speed about 50% higher than the one resorted to in the Lock 12 plant, resulting in the advantage of a less costly generator, and lighter parts to be handled, and indirectly in a saving in cost of installation, overhauling, and replacement. It would be interesting to learn what comparative investigations had taught in connection with the Lock 12 Development, prior to the adoption of the vertical units.

Another point in favor of the horizontal unit is the fact that the gate-operating mechanism, governor connections, etc., permit a much more convenient arrangement.

The question as to the highest efficiency which may be obtained with a scroll casing does not seem to be entirely settled yet; as a matter of fact, turbine runners tested at Holyoke in an open flume have sometimes shown higher and sometimes lower efficiency than they did finally in the plant when installed with the scroll casing for which the runners were originally designed.

Mr. Taylor.

H. BIRCHARD TAYLOR,* ESQ. (by letter).—This very complete paper is a valuable contribution to the literature on modern hydro-electric plants. The progress made in the last few years in this field, particularly in respect to the turbines, has been very marked, but the literature on this subject has not kept pace with it; so that it is a real pleasure to read this paper. It not only describes one of the most modern and prominent developments in the United States, but

* Hydraulic Engr., I. P. Morris Co., Philadelphia, Pa.

Mr. Taylor.

also gives a considerable amount of valuable technical detail, which should prove of interest to engineers.

The writer is particularly interested in this development, as the turbines were designed under his direction. The following comments will be confined to that subject.

The contract for the four 17 500-h.p. turbines was awarded in October, 1912, a short time after the single-runner, vertical-shaft, low-head turbine had come into use, and during the early stages of its development. At that time there had never been constructed a vertical-shaft, single-runner unit of so high a power to operate under a head as low as 68 ft., nor had there been used concrete volute turbine casings under a head as high as 68 ft. In two respects, therefore, the Alabama turbines represent a pioneer development.

Previous to the award of the Alabama contract, there had been a few plants completed or under construction in which the vertical-shaft, single-runner unit had been adopted, and in which the volute casings and draft-tubes were moulded in the concrete. Among these may be mentioned the two plants of the Appalachian Power Company, in Virginia; the plant of the Mississippi River Power Company, at Keokuk, Iowa; and the plant of the Georgia-Carolina Power Company, in Georgia. The turbines in these plants, however, were designed for lower heads and for much lower unit capacities. At this writing, the Alabama units are the most powerful vertical turbines of this type in existence, with one exception; namely, the 20 000-h.p. units of the Laurentide Company, Limited (head 76 ft.).

Table 7 gives a comparison of the powers, heads, and speeds in the plants just mentioned.

TABLE 7.—Comparison of Several Hydro-Electric Plants.

	Head, in feet.	Speed, in revolutions per minute.	Capacity, in horse-power.
Appalachian Power Company, Plant No. 2	49	116	6 000
Appalachian Power Company, Plant No. 4	34	97	3 500
Mississippi River Power Company	32	57.7	10 000
Georgia-Carolina Power Company	27	75	3 125
Alabama Power Company	68	100	17 500

The Appalachian turbines were the first of this type to be put into operation, and the results were so satisfactory that the principal features of their design were adopted for the Alabama turbines, and have been used in a very large majority of recent installations.

The Appalachian turbines were tested after the award of the Alabama contract. The average of the maximum efficiencies secured in two units was found to be 93.7%, which, at that time, seemed almost

Mr. Taylor.

incredible, as this result was about 4% greater than the maximum efficiency secured in the model runner at Holyoke. This increase in efficiency over the model runner, as obtained in the vertical, single-runner setting, however, has been recently confirmed by the tests conducted in the plant of the Mississippi River Power Company, at Keokuk. The efficiency secured in the Appalachian turbines, along with the mechanical simplicity of the vertical-shaft, single-runner unit, has established that type for all important low and medium head installations.

The test of the Appalachian turbines should be of peculiar interest to the engineers of the Alabama Power Company, for the reason that the designs of the runners in the Alabama and Appalachian units were based on the same Holyoke model. As the settings of the turbines in both plants are almost identical, the efficiency of the Alabama units may be assumed to be at least as high as that secured in the Appalachian units, and probably slightly higher, in view of their greater size and higher power.

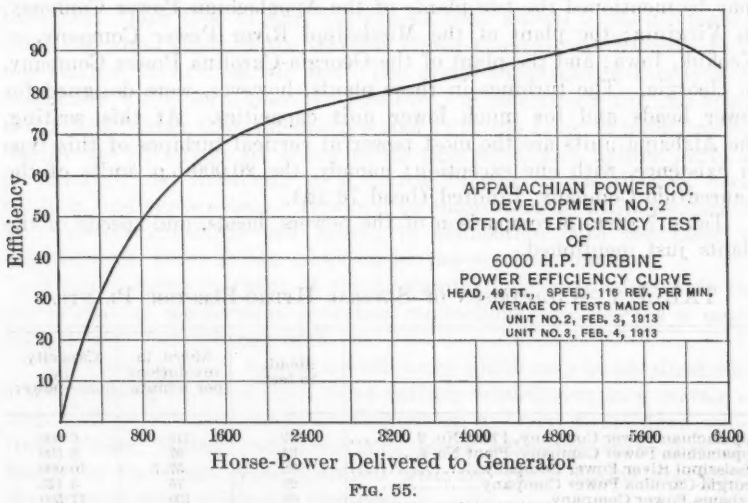

FIG. 55.

Fig. 55 shows the official efficiency curve of the Appalachian turbines. If we revise the horse-power scale, and substitute 17 500 h.p. for 6 000 h.p., the curve may be assumed to apply to the Alabama turbines. When the turbines are tested, it will be very interesting to learn just how closely the efficiencies obtained approach this curve.

During the past 2 years there have been constructed a great number of vertical-shaft, single-runner units for prominent developments —the I. P. Morris Company alone having constructed turbines of this type aggregating approximately 500 000 h.p.—but there have not

Mr. Taylor.

been any new features of importance developed since the design of the Alabama turbines. The lignum-vitæ guide-bearing; the speed ring; the direct-connected operating engines with trunk pistons; the location of the thrust-bearing above the generator; the use of the Kingsbury thrust-bearing; and the pneumatic brakes arranged to act against the lower face of the rotor, etc., have been pretty well accepted as standard details in subsequent work.

The Alabama Power Company was one of the first to adopt the speed ring in connection with concrete volute casings. The design of the speed ring for these turbines was unusual, because of the high head involved. Aside from making the speed ring vanes of sufficient strength, when acting as columns, to carry the weight of the concrete floor above the casing, the weight of the pit liner, generator, and thrust loads down to the concrete below the casing, it was necessary to make them safe when subjected to tension. The rise in pressure in the volute casing during sudden closure of the turbine gates, when added to the already high normal pressure, would tend to lift the concrete floor above the casing, which must be resisted by tension in the speed ring vanes. The speed ring vanes, therefore, were made amply safe to withstand the greatest possible load in either direction which might be imposed.

The use of the speed ring, in connection with the Appalachian turbines, was the subject of considerable adverse criticism. The point was often raised as to whether the speed ring vanes, which are fixed, would not tend to peak the efficiency curve and reduce part load efficiencies. In other words, it was pointed out that these fixed vanes did not conform to the guide-vanes at all gate openings, but were suited to one gate opening only. The Appalachian curve, as shown in Fig. 55, shows no tendency to peak, and the part gate efficiencies cannot be said to be low. It should be remembered that at low gate openings, although the speed ring vanes do not come opposite the guide-vanes, as they do at or near the point of maximum efficiency, the velocity of the water is low, and a comparatively sudden change in the direction of flow when entering the guide-vanes is of no great moment.

It was also argued that the usual experimental outfit in which the Holyoke models are tested is not equipped with speed rings, and, as very high efficiencies have been secured at Holyoke, there is no reason for the use of speed rings in large turbines. Although it is true that very high efficiencies have been secured at Holyoke, the foregoing conclusions are not justified. At Holyoke we have an open flume, in which the velocities are comparatively low, though, in the case of large units with spiral cases, the usual velocities are quite high and represent very much higher percentages of the spouting velocity than those which exist in the Holyoke flume.

Mr. Taylor.

The principal advantages secured in the use of the speed ring are:

1st.—A speed ring insures a uniform direction of flow to all the guide-vanes. Although, as mentioned previously, this is not of importance at low gates, it is at the gate openings at and above those corresponding to maximum efficiency, where the velocities are high.

2d.—The projected area normal to the direction of flow of the speed ring vanes is materially less than that of tie-bolts. The lines of flow, therefore, are interrupted to a less extent by the speed ring vanes than by tie-bolts of circular section. The writer believes that when high velocities are encountered, the projected area normal to the direction of flow is about as important a consideration, as far as losses are concerned, as the actual shape of the tie-piece.

3d.—From an economical standpoint, speed rings are desirable, because without sacrifice in efficiency, they permit higher velocities in the turbine casing, therefore, closer unit spacing and, consequently, a reduction in power-house dimensions.

4th.—The mechanical advantages derived from the use of the speed ring are sufficient for its adoption, aside from any hydraulic advantages. In erection, it is desirable to eliminate machine work and unnecessary fitting in the field. In the construction of the turbine in the shop, the speed ring is put on a boring mill, and, at one setting, is turned to suit the runner band, the lower distributor plate, the head cover, and the lower section of the pit liner, so that, when it is leveled up in the field, the location of all these connecting parts is definitely established.

The advantages which the speed ring offers in securing quick and accurate alignment of the entire turbine during erection, over any design involving separate foundation rings with independent tie-bolts, requiring the separate alignment of each ring, are obvious.

A comparison of the erection costs of two types of turbines, installed simultaneously by the same company, one with speed rings and one with tie-bolts, showed a very marked advantage in favor of the former type. As the units were otherwise similar, the saving in cost as well as the greater speed in erection was attributed to the advantages secured by the use of speed rings.

During the past 2 years the merits of the speed ring have been very generally recognized, and it has been specified by the engineers of a great number of prominent developments. It is interesting to note that the manufacturers who at first argued strongly against its use have recently provided it in connection with some of their contracts.

Mr. Taylor.

The authors' remarks, regarding turbine efficiency guaranties, as stated on page 2221*; are not altogether clear. They state:

"And the manufacturers have guaranteed that the units as installed will have a maximum efficiency of 87% when delivering to the shaft from 15 000 to 17 000 h.p."

This statement should read as follows:

"The manufacturers have guaranteed that the turbines will have a maximum efficiency of at least 87% when delivering a power between 15 000 and 17 000 h.p."

In other words, the turbines are not guaranteed to develop 87% efficiency for all powers between 15 000 and 17 000 h.p., but are guaranteed to develop a peak efficiency of 87%, such peak to occur between the limits of 15 000 and 17 000 h.p.

In making the preliminary studies of the Alabama units, the question of speed was given very careful consideration. The principal features studied in determining the speed were as follows:

1st.—The allowable elevation of the center line of the runner above low tail-water.

2d.—The corrosion of the vanes of high specific speed runners when operated under high heads.

3d.—Part-gate efficiencies.

4th.—Powers developed under heads below normal.

These questions will be considered in order.

1st.—Elevation of Runner Above Tail-Water.—With the development of high specific speed runners, the question of draft-tube design and the allowable elevation of the runner above tail-water has been given very careful attention. Until comparatively recently, it has been thought that the draft-tube was merely a device by which the turbine could be placed a certain distance above tail-water without losing the corresponding head, and it was generally thought that this distance was only limited by the height of the barometric column.

The draft-tube to-day, however, is looked on as one of the most important elements entering into the turbine, especially where high specific speed runners are involved. It is a function of the draft-tube, not only to enable the runner to be placed above tail-water level, but to regain the energy existing in the velocity of discharge from the runner vanes. The off-flow velocity head from high specific speed turbine runners may be as high as 50% of the total head acting on the turbine. The regaining of this velocity head by the draft-tube takes place in the form of a reduction in pressure or an increase in vacuum in the draft-tube, the maximum vacuum occurring immediately below the runner, where the discharge velocity is greatest.

* *Proceedings*, Am. Soc. C. E., September, 1914.

Mr. Taylor.

With a draft-tube of 100% efficiency, the vacuum at the runner is equal to the static draft head or vacuum corresponding to the vertical distance to tail-water level, plus the head corresponding to the velocity of discharge from the runner. The sum of the static draft head plus the velocity draft head must not be greater, theoretically, than the barometric column (34 ft. at sea level). Actually, this sum should not approach this limit by less than 3 or 4 ft. The sum of the static head and velocity head in the draft-tube is, of course, reduced by the losses in the draft-tube and also by the head corresponding to the velocity at the discharge section of the draft-tube, but in modern plants these two elements may be disregarded, as they are kept within negligible values.

The margin between the allowable draft head and the theoretical maximum draft head, is provided principally for regulating purposes. Due to the inertia of the water column in the draft-tube, the sudden closing of the turbine gates increases momentarily the vacuum at the runner, and if this vacuum before closure is already up to the limit, the column of water may leave the runner and then return in a very strong upward surge. In some cases, this upward surge in the draft-tube has resulted in lifting the rotating element of the unit clear from the thrust-bearing.

If flood conditions make it necessary to place a turbine runner, say, 20 ft. above low tail-water level, the velocity draft head at the discharge of the runner at full load should not exceed, say, 10 or 11 ft. With an increase of specific speed, the velocity head through the band, or throat of the runner, must increase, because a runner, to develop a given power, decreases in diameter with an increase in specific speed. Therefore, a specific speed must be selected which will not give a greater velocity head from the runner than that equal to the difference between the 3 or 4 ft. less than the barometric column and the static draft head.

The static draft head of the units at Lock 12; that is, the vertical distance from the center line of the intake to the runner to low tail-water, is 20 ft. With an assumed efficiency, at 17 500 h.p. and 68 ft. head, of 90%, the discharge velocity head from the runner amounts to 10.4 ft. Under the maximum head of 74 ft., at the same gate opening, this velocity head would be increased to approximately 11.3 ft. The resulting maximum draft head possible is, therefore, 31.3 ft.

2d.—The Question of Corrosion as Affected by Specific Speed.—Unfortunately, there is no established law for determining the maximum specific speed allowable for any particular head, aside from that affecting the draft head, which has just been discussed.

As the specific speed of a runner increases, the width across the distributor or intake increases, and the diameter decreases. In addition to the velocity of discharge from the runner increasing with an

Mr. Taylor.

increase of specific speed, there are conditions set up, primarily at part gates, which make runners of this type very much subject to corrosion, caused to a great extent by the radical change in the direction of the flow lines for changes in gate opening.

Aside from the question of draft head, it may be said that the safest method of determining the allowable specific speed for a given head is by consulting a curve drawn between specific speed and head, on which are plotted points corresponding to various installations, which have been in operation for a considerable time and are known to be successful in withstanding corrosion. This curve may be termed the "curve of experience".

In considering turbines for a new development, therefore, the revolutions per minute adopted should not call for a specific speed which would fall to any great extent above a curve thus drawn. It is advisable, of course, to reach out gradually from this curve, or, in other words, to extend our experience, but no great step should be taken at any one time.

At the time of the selection of the speed for the Alabama turbines, it was known that turbines in several installations had successfully withstood corrosion under conditions approximating those which would exist in the Alabama units when operating at a speed of 100 rev. per min.

The next two questions will be considered together:

3d.—The Question of Part Gate Efficiencies as Affected by the Revolutions per Minute of the Unit; and 4th.—Power at Low Heads.—One of the inherent characteristics of the performance of turbine runners is a decrease in the part load efficiencies with an increase in specific speed. There is, of course, a limit to this rule. In other words, by decreasing indefinitely the value of the specific speed and, consequently, the revolutions per minute of the unit, the part load efficiencies apparently cannot be raised above certain maximum values. As far as part load efficiencies are concerned, there seems to be an ideal specific speed by the adoption of which it is possible to obtain part gate efficiencies which cannot be improved on by further decrease in specific speed. The experience of the writer would indicate that this specific speed resulting in an ideal shape of efficiency curve, as far as part gate efficiencies are concerned, lies in the neighborhood of 120 (metric).

Fig. 56 will convey an idea of the manner in which these part gate efficiencies increase with decreased specific speed. The values of the specific speeds shown in this figure are in the neighborhood of that of the Alabama turbines (301.5). It will be noted that Curve *O* is of the highest specific speed, namely 370; that it develops a maximum efficiency of a trifle more than 90%; that the part gate efficiencies are lower than those of the remaining curves, and that

Mr. Taylor.

the point of maximum efficiency occurs nearer full load than is the case with the remaining curves. Curve *M*, with a specific speed of 290, has a much higher part gate efficiency and also a slightly higher maximum efficiency, the point of this maximum efficiency occurring at a lower percentage of full load than on the remaining curves. Curves *A* and *R* represent specific speeds of 301 and 339, respectively. The shapes of these curves are consistent with those of *M* and *O*.

In applying the question of selection of speed directly to the Alabama turbines, it may be of interest to reproduce the performance curves which were discussed with the Alabama Power Company. These curves are shown in Fig. 57. It will be noticed that there are four efficiency-power curves, *M*, *E*, *A*, and *O*. These curves are stepped up from runners designated by these letters. The runners on which these curves are based, when stepped up to give the power indicated, would operate at speeds of 94.8, 100, 100, and 120 rev. per min. in the case of types *M*, *E*, *A*, and *O* runners, respectively.

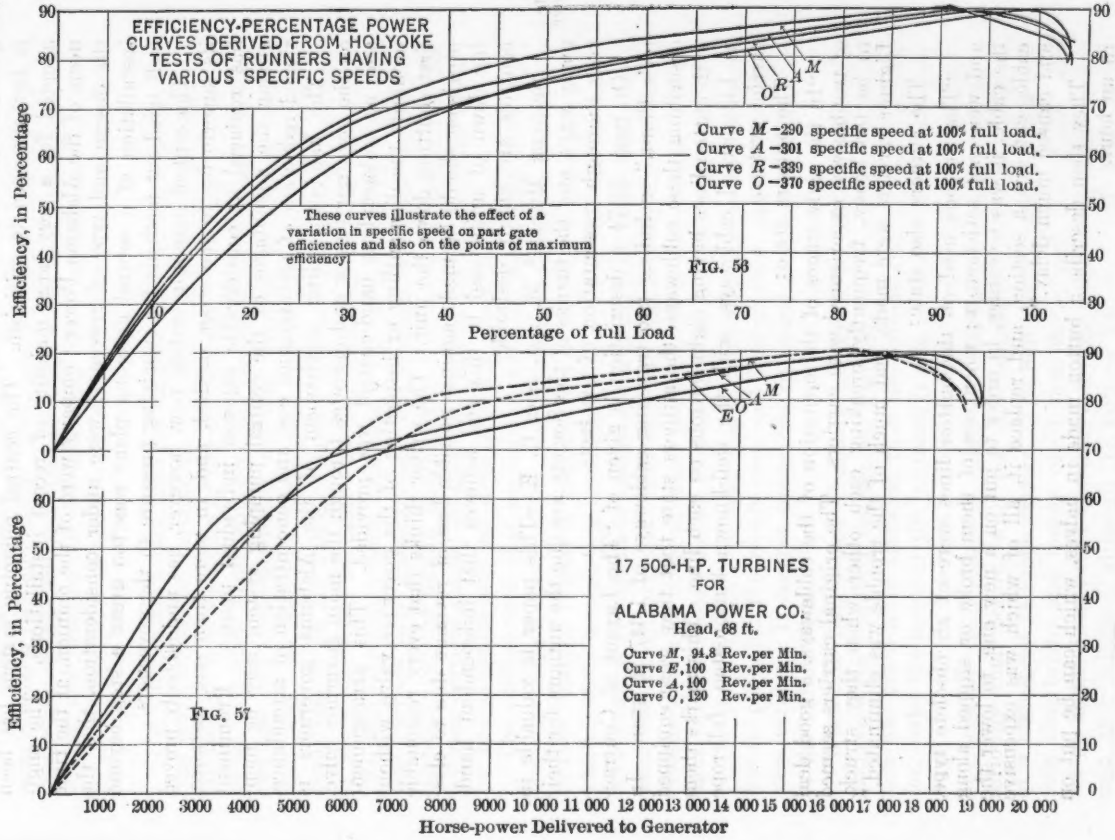
It was decided that though the selection of Type *M* runner would result in extremely high part gate efficiencies, the fact that this runner would not give high power at heads below normal and that the revolutions per minute resulting would necessitate a comparatively expensive type of generator, caused its elimination.

The speed possible with a runner similar to Type *O*, namely 120 rev. per min., was very desirable, but the part gate efficiencies secured were so low, when compared with the others, as to make its adoption unwarranted. Also, the selection of a runner having so high a specific speed would possibly have rendered the runners susceptible to corrosion, as discussed previously (being too great an advance beyond the "curve of experience"); also, it would have been necessary to place this runner at an elevation 5 ft. below that fixed for the runner actually used, and this was found to be objectionable.

The comparative virtues of Runners *A* and *E* were next considered. As both these runners were capable of delivering the same power at the same revolutions per minute, the question of speed, of course, did not figure. The advantage of higher part gate efficiencies of Runner *E* was, it was thought, partly offset by the fact that this runner developed under the lower heads less power than Runner *A*. Further, the dimensions of Runner *E*, when stepped up to the Alabama conditions, resulted in a considerably higher width of distributor, or height of guide-vane. Also, Runner *E*, when enlarged to suit the Alabama conditions, would be materially heavier and, therefore, more costly than Type *A*. The fact that the latter runner made possible a very low width of distributor and a runner of very inexpensive design, and also the fact that it developed under the low head conditions comparatively higher power, resulted in its selection.

One or two thoughts have suggested themselves to the writer in regard to the governors.

Mr. Taylor.



EFFICIENCY-PERCENTAGE POWER CURVES DERIVED FROM HOLYOKE TESTS OF RUNNERS HAVING VARIOUS SPECIFIC SPEEDS
Curve M —290 specific speed at 100% full load.
Curve A —301 specific speed at 100% full load.
Curve R —339 specific speed at 100% full load.
Curve O —370 specific speed at 100% full load.
These curves illustrate the effect of a variation in specific speed on part gate efficiencies and also on the points of maximum efficiency.

Mr. Taylor. The adoption of individual pumps for supplying pressure to the governors in a plant containing as many as four units (six eventually), is perhaps open to criticism. The central pumping system has been adopted for a very large majority of recent installations. The engineers of the Alabama Power Company were of the opinion, at the time the design and type of governors were under consideration, that the installation of a central pumping plant was too great a step beyond well tried-out methods for supplying pressure to the governors.

The central pumping system now, however, has undoubtedly proved its superiority to the other method, and, in more than one instance, has replaced at considerable expense individual pumps. Prominent among the advantages of the central pumping system may be mentioned reduction of maintenance cost and concentration of attendance.

The hand-controlling mechanism of the Alabama governors is on the governor proper and operates through the main governor valve, and no independent hand-control was provided. This arrangement prohibits the dismantling or inspection of the governor valve without first shutting down the unit. The writer thinks that every reasonable provision should be made against possible loss of revenue due to closing down of units, and to this end believes that independent hand-controls are highly desirable.

Mr. Miller. SPENCER MILLER,* M. AM. SOC. C. E.—This paper is valuable in many ways, and the thanks of the Society are due the authors for their very thorough presentation of the facts.

On page 2247† a description is given of "The Layout of Contractor's Plant," including two traveling cableways of 1 647 ft. span. In describing these cableways, the authors state that they were equipped with button lines having eight buttons on each line. This marks them as Lidgerwood cableways, with the well-known button-stop, fall-rope carrier system.

The authors state:

"In the early stages of the operation of the cableways, a good deal of trouble was experienced with carriers. The original carriers seemed to be too heavy, frequently breaking each other when they struck. Lighter carriers were made, and much of the trouble was eliminated."

The authors also state:

"The buttons used on the button lines were of an obsolete type, and were not satisfactory; when one of them broke or slipped along the cable, it was necessary, in order to put on a new one, to lower the cable, cut out a section, and replace it, all of which was expensive and caused much delay."

They then describe a button made in halves, which can be put on in an hour.

---

* New York City.

† *Proceedings*, Am. Soc. C. E., September, 1914.

Mr. Miller.

Again, the authors state:

"The cableways handled practically 60% of the concrete, and were run both day and night. They also handled practically all the excavation in the early stages of the work. They were used for moving and erecting all derricks, etc., handling form lumber, iron, and materials of a like character, and were found to be exceedingly useful for the latter purpose."

The authors have said that the buttons used for spacing the fall-rope carriers were of the obsolete type, and it is probably true that the fall-rope carriers were also of the obsolete type. The results, no doubt, would have been wholly different had the modern high-speed cableway carriage and shock-absorbing fall-rope carriers, as well as buttons, been used. As indicated in the paper, the efficiency of a cableway depends largely on the fall-rope carrier system. The system mentioned by the authors was probably identical with that used on the Chicago Drainage Canal on twenty cableways. The repair costs for these fall-rope carriers were considerable. The constant attention required in strengthening the button fastenings and the slots in the head of the fall-rope carriers showed an inherent fault in the design. The remedy for this difficulty was not discovered for many years.

The authors state that the carriers were too heavy and broke when they struck each other. This they say was remedied by making the carriers lighter. Impact is in proportion to weight. A fall-rope carrier which is light is weak, and one which is heavy is strong. If the design is the same, it is difficult to understand why the light ones do not break when the heavy ones do. Probably the lighter ones did not break because they were made of better material. It is also possible that the light carriers worked better because they were better proportioned.

On the Chicago Drainage Canal, with carriage speeds of about 800 ft. per min., the repair costs and loss of time, due to breakages, were serious. It seemed impossible to secure the buttons effectively to the button rope.

When the Lidgerwood Company undertook to build the thirteen cableways for handling concrete at Panama, no part of the construction was given more attention than the buttons and fall-rope carriers, for, under the terms of the contract, it was necessary to run the cableways at 1 850 ft. per min. These carriers, which for so many years had been the chief source of delays on cableways, were taken up more seriously than before, with the determination to solve the problem of a high-speed fall-rope carrier. The best carriers and the best buttons that brains and money could then devise were constructed and set up at the Lidgerwood Company's testing station. At 1 100 ft. per min. they collapsed, although the buttons held fast. All kinds of the toughest metals were used, and yet after weeks of experiment it was impossible to obtain anything that would withstand the shock of the

Mr. Miller.

button at a speed in excess of 1 150 ft. per min. Finally, after weeks of trial and continual rebuilding, the shock-absorbing principle was invented. The head of the fall-rope carrier was hinged instead of being rigidly connected to the body of the carrier. The button collided with a swinging eye instead of an elongated slot, and, instead of colliding at two points on opposite sides of the button, collided almost throughout its entire diameter.

As soon as this construction had been set in motion, a speed of 3 000 ft. per min. was developed, and the old law, that the impact was in proportion to the weight and increased as the square of the velocity, was emphasized in an unusual manner.

What the authors' conclusions would have been had the new shock-absorbing carrier and carriers been used is not difficult to anticipate.

The cableway engines used did not embody the numerous improvements now in use by the manufacturers of those engines, such as improved cylinder design and construction, larger, heavier, and better balanced reciprocating parts, etc., all resulting in higher speed and efficiency.

The obsolete buttons which the authors refer to were secured by a through pin and bearing in solder or Babbitt. The new buttons are taper-bored, the strands of the rope being opened and a tapered pin inserted. The taper of the bore and the pin is the same, and is less than the angle of repose. No other pin is used. The more the carriers hammer the buttons, the tighter the fastening. At Panama heavy jacks were necessary to remove the buttons after they had been in service for several months. The new buttons do not slip, and do not injure the button rope. Button ropes now frequently last four and five years. Therefore, the necessity for a divided button is not apparent.

The official reports at Panama show that these cableways at Gatun were kept at an efficiency of 99 per cent. Expressed in other terms, the entire cableway was ready for operation 99 min. out of every 100 they were called on for service, during the period recorded, and that applies not only to the fall-rope carriers, but to every part of the cableway. The efficiency of the new fall-rope carriers, therefore, can confidently be stated to be even in excess of 99 per cent.

On page 2275,* the authors state:

"A cableway is not satisfactory in handling excavated materials, as it is not only expensive, but slow."

They also state:

"The writers are of the opinion that, as a rule, the cableway should be restricted to moving plant, derricks, forms, and general work, and also such concreting as is advantageous to place with it, and that it

* *Proceedings*, Am. Soc. C. E., for September, 1914.

should not be made the main method for the transportation of all materials on the job, as it was here." Mr. Miller.

Among those who use cableways extensively for concreting operations, it is a common expression that the cableway is worth its investment merely for the purposes of moving plant, forms, etc., but the experiences of the Isthmian Canal Commission with cableways at Gatun Locks, Panama, by the John F. Casey Company, at Aspinwall, Pa., and Cleveland, Ohio, and by the H. E. Talbott Company, Grand Mére, Que., Canada, hardly bear out the conclusions of the authors.

The authors state that the record for a 10-hour run with the cableways was seldom more than 400 cu. yd. Does this mean 400 yd. for two cableways? At Panama runs as high as 60 cu. yd. per hour, with one cableway handling 2-yd. batches, were recorded. The John F. Casey Company, on thin section baffle walls, 6 ft. 9 in. wide at the bottom and 2 ft. wide at the top, has laid as much as 692 cu. yd. per day with one cableway. The H. E. Talbott Company placed, with one cableway, from 320 to 350 cu. yd. of concrete, with a travel of 1 100 ft., in 10 hours. Some extraordinary records are being made at Cleveland, Ohio, at present, by the John F. Casey Company. No other device will do what the cableway is adapted for, namely, handling excavation, placing concrete and large rock, moving forms, timber, derricks, and miscellaneous material, such as ironwork, etc. If time was limited, there is no reason why three or four cableways should not have been used.

In dam construction, also, there is nearly always the menace of high water during a part or all of the construction period. No device presents such effective insurance against that danger as the cableway. It stands safe throughout, and for removing auxiliary plant and material quickly when occasion demands, it is always ready. The speaker believes that had the latest type of high-speed cableways been used on this work, the authors would have modified their deductions.

W. E. Mitchell,* Esq. (by letter).—Referring to the discussion by Mr. R. D. Coombs, on this subject, Mr. Coombs, of course, did not know, what the authors of this paper knew, namely, that it is the intention to have a paper, discussing the purely electrical side of the development in Alabama, written by the Electrical Engineer for the American Institute of Electrical Engineers. When this paper comes out it will answer a number of the points raised by Mr. Coombs. Mr. Mitchell.

It may be stated here, however, that probably more attention than usual was given to the subject, not only of the transmission line voltage, but of the style and size of lines for both transmission and distribution. These matters were gone into very thoroughly, following

* Operating Mgr., Alabama Power Co., Birmingham, Ala.

Mr. Mitchell.

a careful survey of all high-tension systems in operation at the time, with the definite idea of making the service as reliable as possible.

Following out this idea, Birmingham, which of course is the main distributing point, is supplied by three 110 000-volt circuits, two by one route going practically direct to the city limits, and the third by an entirely separate route, so that the likelihood of interruptions due to severe storms in one locality will be minimized.

As stated in the paper, the transmission-line voltage is 110 000 volts, and the distribution lines are practically all of 22 000 volts. The middle cross-arm should have been given as being 5 ft. longer than the top and bottom cross-arms, making the offset of the middle wire 2 ft. 6 in.

The writer cannot agree with Mr. Coombs' statement that the high towers will not permit of the longer spans in rough country. There are times, of course, when considerably shorter spans are made necessary by intervening hills, but in general it was found in Alabama that with Type A towers the average span was 700 ft., and that in very few cases did it drop below this, although it was frequently as much as 750 or 800 ft.

The Type C towers, which, as a matter of fact, were used in the flat country, were not purposely designed for this work, but with the idea that steel-core aluminum would be used on their lines, as this called for less sag and for anchor towers at least every tenth tower. After the towers were ordered, however, it was decided to use copper, and hence the spacing had to be reduced. In general, a higher tower would be more economical in flat country. The Type C tower was designed light on purpose, as it would have been impossible to have anchored the steel-core aluminum at every tower, and it was the idea to anchor it at every tenth tower on an extra heavy Type B tower.

In regard to the specifications covering clearance and loading, a very careful investigation of the climatic conditions in Alabama was made, and it was found that only about three times in the last 20 years had conditions been such that sleet would have been formed; therefore it is thought that the use of $\frac{1}{4}$ in. of ice and 8 lb. of wind pressure was sufficiently conservative. The standard tower was used on all spans, as it was found to be still well within safe limits. Excessively long spans were purposely avoided in order that there would be no special construction, always extremely expensive. The only special towers used on the whole work were four for two river crossings, and the dead-end towers at each sub-station.

Referring to the criticism of distribution lines built on wooden poles, this also received careful consideration, and investigation of the life of creosoted poles throughout the South was made. Long-leaf yellow pine is extremely plentiful in this district and it was found

Mr. Mitchell.

that poles treated with 12 lb. of creosote showed no deterioration after 20 years. These poles proved to be very much cheaper than steel, although for comparative purposes, the company has actually put in one 25-mile line with flexible towers. This ran up the cost, however, to about 15% more than the same line built on creosoted poles. The writer does not believe that the steel poles would have enough longer life than the creosoted poles to justify them.

The size of the conductors on the 22 000-volt lines varies from No. 4 to No. 00 copper. The standard spacing, using creosoted, long-leaf, yellow pine cross-arms, is 5 ft. horizontally and 3 ft. 6 in. vertically between conductors. This is believed to be a more liberal spacing than is ordinarily used.

The writer was on this development from the commencement of the work, and has had the opportunity to be in direct charge of the operating from the time it went into commission up to the present date. During the past lightning season there was considerable trouble from punctured insulators, and one more disk is now being added to all strings. The entire system is now being inspected, and all insulators are being tested with a megger. It is believed that this will eliminate much of the trouble in the coming lightning season. On the distribution lines, where a 35 000-volt pin insulator has been used, there has been practically no trouble whatever.

The generating plant has worked out fully up to the expectations, with regard to simplicity of design, and has proved a good station to handle, from the operating point of view.

MEMOIRS OF DECEASED MEMBERS

NOTE.—Memoirs will be reproduced in the volumes of *Transactions*. Any information which will amplify the records as here printed, or correct any errors, should be forwarded to the Secretary prior to the final publication.

EDWARD COOK BURNS, M. Am. Soc. C. E.*

DIED OCTOBER 29TH, 1914.

Edward Cook Burns, the son of Barclay J. and Isabella Cook Burns, was born on January 30th, 1845, near the corner of Chambers Street and Broadway, in New York City, where his father was engaged in publishing and newspaper work. When the boy was three years old, his mother died, and he was taken to live with his grandmother at Jamestown, N. Y.

He received his early education in private schools at Jamestown, and was afterward sent to the Patterson Preparatory School in Detroit, Mich., where he was prepared for the Civil Engineering School of the University of Michigan from which he was graduated with the Class of 1868. Among his close friends and associates at the University were G. H. Benzenberg and the late Alfred Noble, Past-Presidents, Am. Soc. C. E., and Charles F. Brush, the inventor of modern electric lighting.

Mr. Burns had been employed during his summer vacations, from 1865 to 1867, as Assistant with the United States Lake Survey. In August, 1868, he was appointed Levelman on the Rockford, Rock Island and St. Louis Railway, remaining in that position until January, 1869, when he was made Division Engineer. From May to December, 1870, he was employed as Assistant Engineer on the Central Railroad of Iowa, and from April to July, 1871, as Division Engineer on the Burlington, Cedar Rapids and Minnesota Railroad.

Mr. Burns then returned to the East as Engineer in Charge of the extension of the Pittsburgh, Bessemer and Lake Erie Railroad until May, 1872, when he was appointed Assistant Engineer in charge of the construction of the Buffalo and Southwestern Railroad, from Gowanda to Jamestown, N. Y., under General Robert Ewing. From April, 1873, to August, 1874, Mr. Burns served as Acting Superintendent of the Jamestown Gas Light Company. In August, 1874, he returned to the Buffalo and Jamestown Railroad as Assistant Engineer, which position he retained until June, 1875.

From 1877 to 1885, he was employed as United States Assistant Engineer on river and harbor improvements at various places, including such important works as the construction of the Sault Ste. Marie

* Memoir prepared by the Secretary from information on file at the Society House.

Canal, the improvement of the St. Clair Flats Canal, the dredging of the Livingston Channel, etc., etc.

In 1885, Mr. Burns returned to Jamestown, N. Y., where, until his death on October 29th, 1914, after a year's illness, he was engaged in private practice as a Consulting Engineer. He was connected with many of the principal construction enterprises in Jamestown and the surrounding country, having served as Engineer of the Board of Public Works from 1894 to 1898. He was also one of the Conewango Swamp Drainage Commissioners and had charge of the construction of its line for the Chautauqua Traction Company. He was always in demand throughout the vicinity as an expert in the design and construction of highway and railroad bridges, and had planned and supervised the construction of the old and new Boatlanding Bridges and also the new Winsor Bridge, the latter two having been his last important work before ill-health compelled him to give up active practice.

On October 3d, 1872, Mr. Burns was married to Mary Graham, daughter of Major Thompson Graham, of Mercer, Pa., who, with one daughter, survives him.

Mr. Burns was a man of strong character and high ideals, who gave to his work his best thought and action. His strict integrity is shown in the character of his work, which was never slighted or cheapened to accomplish a temporary effect. He had a well-stored mind and, being fond of books and study, kept up with the advances and improvements of his profession. He was always considerate and courteous to every one, and will long be remembered by his friends and those who were closest to him for his pleasing personality, his kindly spirit, and his desire to add to the pleasures rather than the burdens of those with whom he was associated.

He was a member of the Delta Kappa Epsilon Fraternity and a Thirty-second Degree Mason.

Mr. Burns was elected a Member of the American Society of Civil Engineers on July 5th, 1882.

HURD CLARENCE HURD, M. Am. Soc. C. E.*

DIED JULY 8TH, 1914.

Hurd Clarence Hurd was born at Helena, Tex., on April 16th, 1870. The early years of his life were spent in a community in which the Spanish language was spoken to a considerable extent. He acquired a knowledge of this language at that time and afterward perfected it

* Memoir prepared by Wendell M. Reed, M. Am. Soc. C. E.

in high school and university, making much use of it throughout his professional career.

He was graduated with the degree of C. E., from Princeton University, in June, 1893. His first work was in connection with the Sewer Department of Washington, D. C. In 1897, he went with the Nicaraguan and Isthmian Canal Commissions as Instrumentman, but at the end of the first year of his engagement he became First Assistant to the Chief Hydrographer, holding this position until 1901. Although this work was interesting, and developed individual initiative, it was also fraught with hardships, and Mr. Hurd, besides experiencing the minor troubles, also suffered an attack of yellow fever. That he came out of this country not completely broken in health, was a strong testimonial of his rugged constitution and temperate manner of living.

In September, 1902, he was appointed a Special Agent of the State Department, in Nicaragua and Costa Rica. In 1903, he became attached to the United States Reclamation Service, and spent the next two years in charge of important surveys and construction of canals, dams, and irrigation systems in Arizona, California, New Mexico, and Montana.

In 1905, the call of the South again reached him, and he went to Peru as Chief of the Hydraulic Commission for the study of irrigation. The Peruvian Government having requested the recommendation of a suitable person for this position, Mr. Hurd was named by the United States Government.

In 1907 Mr. Hurd returned to the United States and took up hydro-electric work in California. He followed this line of work for five years and, during that time, had charge of the construction of several important hydro-electric developments. His skill in reconnoissance surveys and plans gave him such a standing that he was employed, in 1912, by the Ebro Irrigation and Power Company, to take charge of the location, design, and construction of a large lined power canal, aqueducts, siphons, etc., in Spain.

He was in charge of this work for about one year when the general financial depression compelled its cessation. Mr. Hurd then returned to the United States and was taking a much needed rest when he accidentally met his death by drowning in Chesapeake Bay.

Mr. Hurd was modest and unassuming in manner, but soon impressed those with whom he came in contact with his sterling worth, and professionally he ranked very high.

He was married in 1905 to Miss Grace Lewis, of Roswell, N. Mex., who, with four children, survives him.

Mr. Hurd was elected a Member of the American Society of Civil Engineers on July 2d, 1913.

PAPERS IN THIS NUMBER

"THE WATER-PROOFING OF SOLID STEEL-FLOOR RAILROAD BRIDGES." SAMUEL TOBIAS WAGNER. (To be presented Jan. 6th, 1915.)

"NOMOGRAPHIC SOLUTIONS FOR FORMULAS OF VARIOUS TYPES." R. C. STRACHAN. (To be presented Feb. 3d, 1915.)

PROGRESS REPORT OF THE SPECIAL COMMITTEE ON MATERIALS FOR ROAD CONSTRUCTION AND ON STANDARDS FOR THEIR TEST AND USE. (To be presented Jan. 20th, 1915.)

PROGRESS REPORT OF THE SPECIAL COMMITTEE ON STEEL COLUMNS AND STRUTS. (To be presented Jan. 20th, 1915.)
